INFORMATION TO USERS

This material was produced from a microfilm copy of the original document. While the most advanced technological means to photograph and reproduce this document have been used, the quality is heavily dependent upon the quality of the original submitted.

The following explanation of techniques is provided to help you understand markings or patterns which may appear on this reproduction.

1. The sign or "target" for pages apparently lacking from the document photographed is "Missing Page(s)". If it was possible to obtain the missing page(s) or section, they are spliced into the film along with adjacent pages. This may have necessitated cutting thru an image and duplicating adjacent pages to insure you complete continuity.
2. When an image on the film is obliterated with a large round black mark, it is an indication that the photographer suspected that the copy may have moved during exposure and thus cause a blurred image. You will find a good image of the page in the adjacent frame.
3. When a map, drawing or chart, etc., was part of the material being photographed the photographer followed a definite method in "sectioning" the material. It is customary to begin photoing at the upper left hand corner of a large sheet and to continue photoing from left to right in equal sections with a small overlap. If necessary, sectioning is continued again -- beginning below the first row and continuing on until complete.
4. The majority of users indicate that the textual content is of greatest value, however, a somewhat higher quality reproduction could be made from "photographs" if essential to the understanding of the dissertation. Silver prints of "photographs" may be ordered at additional charge by writing the Order Department, giving the catalog number, title, author and specific pages you wish reproduced.
5. PLEASE NOTE: Some pages may have indistinct print. Filmed as received.

Dedication

To Pamela, Daniel, and Lorien Carsey

ACKNOWLEDGEMENT

I wish to express my sincere appreciation to Dr. Sean P. McGlynn under whose direction this work was performed. I would also like to thank present and past members of Dr. McGlynn's Research Group for their discussions and suggestions.

This work was supported by the United States Atomic Energy Commission-Division of Biomedical and Environmental Research--Physics and Technological Program and the Louisiana State University. Financial assistance in preparation of this dissertation was provided by the Charles E. Coates Memorial Fund of Louisiana State University Foundation donated by George H. Coates. This support and assistance is gratefully acknowledged.

Finally, I express my gratitude to my wife, Pam, and to our children, for their patience and inspiration during the years of my graduate work.

Foreword

This dissertation is divided into two sections:

Section A: This Section consists of Chapter 1 only. It is concerned with the absorption and emission spectroscopy of o-, m-, and p-isomers of various disubstituted benzenes, one substituent being an electron donor and the other an electron acceptor.

Section B: This section consists of Chapters 2 and 3. It is concerned with the absorption and emission spectroscopy of several small inorganic ions and with the development of a quantum-mechanical model of singlet-triplet transition intensities in the silver nitrite molecule.

Abstract

The absorption and emission of a number of highly-polar molecules of the type D- ϕ -A, where D is an electron-donor substituent, ϕ is a benzene ring, and A is an electron-acceptor substituent, have been investigated. The electronic spectra of o-, m-, and p-fluorobenzonitriles, cyanoanisoles, cyanoaniline, aminoacetophenone, and nitroaniline are presented in detail. For the weakly-polar fluorobenzonitriles, the lowest-energy absorption band consists of only one 1L_b -related transition. For the more-polar cyanoanisoles and the highly-polar cyanoanilines, aminoacetophenones, and nitroanilines, the lowest-energy absorption band of the p-isomer is shown to be a composite of at least two transitions. The more intense 1L_a -related band is of higher energy than the 1L_b -related band, but undergoes an energy decrease as the polarity of the molecule increases.

The lowest-energy band of the o- and m-derivatives consists of only one 1L_b -related transition. The second intense band of the o- and m-derivatives consists of one 1L_a -related transition. Both of these transitions undergoes an energy decrement as the polarity of the molecule increases. In all o- and m-molecules, fluorescence is shown to be the inverse of the 1L_b -related absorption.

The trends observed in these five D- ϕ -A sub-sets have been qualitatively investigated in a large selection of other disubstituted

benzenes. The 1L_a - and 1L_b -related bands display considerable regularity of energy and intensity trends. In a sufficiently polar p -derivative, the 1L_a -related band may coincide with or even drop below the 1L_b -related band, with significant effects on the emission characteristics. Because of symmetry, the 1L_a -related band in the p -derivatives is very strongly affected by substituents whereas the 1L_b -related band is not. With strong electron donors and acceptors, the 1L_a -related band acquires more charge-transfer character. In the o - and m -derivatives, on the other hand, the charge-transfer effect of the substituents is shared somewhat equally by both the 1L_b - and 1L_a -related bands.

Quantum-chemical calculations on a representative sampling of o -, m -, and p -derivatives are presented and analyzed. The degree of charge-transfer, the energies and the intensities of the various electronic transitions are examined. Considerable attention is also devoted to singlet-triplet intervals and ground state dipole moments.

The excited states of simple metal ion - inorganic cation complexes have been investigated. Two mechanisms which rationalize the non-additivity of certain absorption bands in the spectra of these complexes are described: charge-transfer transitions and enhanced singlet-triplet transitions. The latter effect is more likely to be present if the cation is a heavy-metal ion.

The electronic spectra of the chlorite and sulfate ion have been investigated. In the spectrum of the chlorite ion, a transition is observed which is interpreted as a singlet-triplet transition. An examination of the electronic spectrum of the sulfate ion reveals a previously unreported transition which is identified as a singlet-triplet transition.

The tungstate and molybdate ions are known to emit in the solid phase. In the solution spectra of salts of these anions, a previously unreported transition is observed which resembles the emission excitation band. This transition is examined and interpreted as a singlet-triplet transition of the anion.

A model which describes the interaction between a metal cation and an inorganic anion is developed using first-order perturbation theory. The model does not invoke vibronic spin-orbit coupling. All one-electron excitations of the highest-occupied and lowest-occupied metal and anion orbitals are investigated. Expressions which describe all sources of $S_0 \rightarrow T_1$ intensity are derived and given. These expressions are computed for the silver nitrite molecule and are compared with experiment. The results indicate the critical role of charge-transfer transitions in the mechanism of the enhancement of $T_1 \rightarrow S_0$ probabilities.

CHAPTER ONE,
THE EXCITED ELECTRONIC STATES
OF POLAR AROMATICS

Abstract

The absorption and emission of a number of highly-polar molecules of the type D- ϕ -A, where D is an electron-donor substituent, ϕ is a benzene ring, and A is an electron-acceptor substituent, have been investigated. The electronic spectra of o-, m-, and p-fluorobenzonitriles, cyanoanisole, cyanoaniline, aminoacetophenone, and nitroaniline are presented in detail. For the weakly-polar fluorobenzonitriles, the lowest-energy absorption band consists of only one 1L_b -related transition. For the more-polar cyanoanisoles and the highly-polar cyanoanilines, aminoacetophenones, and nitroanilines, the lowest-energy absorption band of the p-isomer is shown to be a composite of at least two transitions. The more intense 1L_a -related band is of higher energy than the 1L_b -related band, but undergoes an energy decrease as the polarity of the molecule increases.

The lowest-energy band of the o- and m-derivatives consists of only one 1L_b -related transition. The second intense band of the o- and m-derivatives consists of one 1L_a -related transition. Both of these transitions undergoes an energy decrement as the polarity of the molecule increases. In all o- and m-molecules, fluorescence is shown to be the inverse of the 1L_b -related absorption.

The trends observed in these five D- ϕ -A sub-sets have been qualitatively investigated in a large selection of other disubstituted benzenes. The 1L_a - and 1L_b -related bands display considerable regularity of energy and intensity trends. In a sufficiently polar p-derivative, the 1L_a -related band may coincide with or even drop below

the 1L_b -related band, with significant effects on the emission characteristics. Because of symmetry, the 1L_a -related band in the p-derivatives is very strongly affected by substituents whereas the 1L_b -related band is not. With strong electron donors and acceptors, the 1L_a -related band acquires more charge-transfer character. In the o- and m-derivatives, on the other hand, the charge-transfer effect of the substituents is shared somewhat equally by both the 1L_b - and 1L_a -related bands.

Quantum-chemical calculations on a representative sampling of o-, m-, and p-derivatives are presented and analyzed. The degree of charge-transfer, the energies and the intensities of the various electronic transitions are examined. Considerable attention is also devoted to singlet-triplet intervals and ground state dipole moments.

I. INTRODUCTION

Disubstituted benzenes of the type D- ϕ -A (where D represents a donor and A an acceptor substituent) constitute a sub-set of the broad class of organic compounds which exhibits large ground state dipole moments. The electronic spectroscopy of this subset has been discussed in terms of substituent effects on benzene¹⁻⁵, solvent^{6,7} and steric⁸⁻¹¹ effects on electronic transitions, the relevance of intramolecular charge-transfer concepts¹²⁻¹⁸, electrically-induced dichroism¹⁹⁻²⁷, etc. No general understanding of the electronic structure of these molecules seems to be available.

The D- ϕ -A sub-set is prototypical of the highly-polar aromatics. It also has the advantage that substituents may be varied systematically so that a series of molecules of increasing polarity may be generated. This last property is the major reason for our choice of this sub-set.

Our interest lies in the way in which the properties of the lower-energy singlet and triplet states depend on the molecular polarity. The approach we adopt is correlative. We begin with a discussion of experimental data for five representative ortho, meta and para (omp) triads which span the weakly-polar to highly-polar range of D- ϕ -A species. Our aim is to categorize those general absorptive and emissive characteristics which, within a given triad, appear to be a function of molecular polarity. Thereafter, we present an extensive set of data for a great variety of omp triads; The aim, in this instance, is to discern those characteristics of the ortho (or meta, or para) series which are distinctly dependent on the molecular

polarity. Finally, the same molecules are subjected to quantum chemical processing in order to gain insight into the nature of the regularities displayed by the empirical data.

This work, then, is an attempt to systematize the experimental and theoretical results. To this end, we ask the following questions:

---Do any electronic and spectroscopic regularities exist among the members of the D- ϕ -A sub-set?

---What are the effects of molecular polarity on the absorption and emission characteristics of these molecules?

---Can the empirical regularities be formulated in a theoretical way?

---Is molecular polarity the best and/or the most convenient independent variable for the observed correlations?

The results of this work may be of interest for a number of reasons. Firstly, the class of highly-polar aromatics contains a large number of biological molecules. Secondly, many of the extrinsic chromophores (or "fluorescent probes") which are used to gauge micro-environments within macromolecules²⁸⁻³¹ fall in this category. And, thirdly, the ability to vary the fluorescence energy and polarization by merely altering the solvent medium, and the possibility that many of the excited states possess very large static dipole moments (30D or larger), may well be of technological advantage.

II. EXPERIMENTAL METHODS

All compounds were recrystallized from ethanol and/or vacuum sublimed until no further change of the absorption spectrum was detectable. Solvents were purified as follows: Ethanol was refluxed over calcium oxide and distilled from magnesium turnings; methyl-

cyclohexane (MCH) and 3-methylpentane(3MP) were washed with fuming sulfuric acid and water, passed through a silica gel column and distilled over sodium wire; and ether, which was maintained in slow reflux over sodium wire, was drained off as needed.

Absorption measurements, whether at 300 or 77°K, were made with either a Cary-14 or Cary-15 spectrometer. Emission measurements, usually at 77°K, were recorded with a Jarrel-Ash Mark V 0.5m scanning monochromator, used in conjunction with a PAR phase-sensitive detection system, a 500W Xenon arc source, and a Cary 15 fl8 excitation monochromator. Luminescence spectra were corrected for the response properties of the detection system. All luminescing samples were optically homogeneous and were thoroughly degassed by repeated freeze-thaw-evacuate cycles. Solute concentrations were less than $10^{-4}M$ in all instances, in order to minimize aggregation and inner-filter effects.

Polarization measurements were performed using the techniques of Azumi and McGlynn³². The EPA solvent, which forms an excellent glassy solution at 77°K, consists of ether, isopentane and alcohol in a 5/5/2 (by volume) mixture.

III. EXPERIMENTAL RESULTS

The series of D- ϕ -A molecules may be ranked according to molecular polarity by using the substituent activation of the benzene ring toward electrophilic substitution as a gauge. This gauge classifies substituents according to the direction and degree of induced electron migration in the following manner³³.

<u>Electron Donors</u>		<u>Electron Acceptors</u>	
increasing donor character ↓	-CH ₃	increasing acceptor character ↓	-CN
	-F		-COOH(-COOR)
	-Cl		-COCH ₃
	-Br		-CHO
	-OH		-NO ₂
	-OCH ₃		
	-NH ₂		
	-O ⁻		
	-N(CH ₃) ₂		

Three distinct types of series, all ranked according to increasing molecular polarity, may be defined:

---SERIES A: The electron donor and the electron acceptor are both held constant, while their relative positions (i.e., ortho, meta or para) are varied;

---SERIES B: The electron donor is held constant, while the electron acceptor is varied; and

---SERIES C: The electron acceptor is held constant, while the electron donor is varied.

We will discuss Series A first. We consider five OMP triads taken in order of increasing polarity: Fluorobenzonitriles, cyanoanisoles, cyanoanilines, aminoacetophenones and nitroanilines.

A. SERIES A.

1. FLUOROBENZONITRILES: The fluorobenzonitriles are weakly-polar. The spectra of the omp triad are given in Figures 1 and 2. The following observations may be made:

Figure 1.
Absorption spectra of o-, m-, and p-fluorobenzonitrile in ethanol at room temperature.

Figure 2.

Total emission spectra of o-, m-, and p-fluorobenzo-nitriles in ethanol glass at 77°K. The spectra are corrected for all instrument parameters.

---The absorption spectra of all three omp members are almost identical and very similar to that of benzene. An even closer similarity exists between the omp spectra and that of benzonitrile. This is as expected: Fluorine, according to our criterion, merely functions as a weak perturbation to the benzene ring.

---The $36,000\text{cm}^{-1}$ band (${}^1L_b \leftarrow {}^1A$) is of lower intensity and slightly higher energy in the para-isomer. The $44,000\text{cm}^{-1}$ band (${}^1L_a \leftarrow {}^1A$) is of slightly lower energy and slightly higher intensity in the para isomer. The details of these two transitions are collected in Table 1.

---The ${}^1L_a - {}^1L_b$ band gap is quite large (7000cm^{-1}) for all three isomers but is smallest for the para-isomer.

---No evidence of new transitions to or from orbitals localized on the substituents (charge-transfer), or of $n \rightarrow \pi^*$ transitions is found at wavelengths greater than 200nm.

---Fluorescence is a "mirror image" of the $36,000\text{cm}^{-1}$ band (${}^1L_b \leftarrow {}^1A$) in every case. The lifetimes and quantum yield data are also presented in Table 1. The intrinsic emissive lifetimes obtained from the fluorescence data are 50, 46 and 14ns for o, m and p, respectively. The same lifetimes obtained from absorption data³⁴ by assuming that fluorescence is the inverse of the lowest-energy absorption event, are 56, 57 and 180ns, respectively. It is concluded that the fluorescence is ${}^1L_b \rightarrow {}^1A$ in nature.

---The phosphorescence possesses more vibronic structure than the fluorescence. The triplet state, in all three isomers, may be assigned as 3L_a because of its energetic similarity to the 3L_a state of benzene ($29,500\text{cm}^{-1}$).

^a Absorption measurements were made in ethanol at 298°K; emission studies were made in ethanol at 77°K. The experimental error is 50 cm^{-1} . The symbol ϵ refers to extinction coefficient (in $\ell \text{ mole}^{-1} \text{ cm}^{-1}$) and the symbol f refers to oscillator strength. The subscripts P and F refer to phosphorescence and fluorescence, respectively.

---The larger ϕ_P/ϕ_F value for p-fluorobenzonitrile is the result of a greater rate constant for intersystem crossing (k_{ISC}) and a smaller rate constant for fluorescence (k_F), both of which act to produce a relative decrease of ϕ_F in the p-isomer.

For further details on the fluorobenzonitriles, consult Lui and McGlynn³⁵.

2. CYANOANISOLES: The cyanoanisoles are moderately polar. The spectra of the omp triad are given in Figures 3 and 4. The following general observations may be made:

---The absorption spectra of o and m are similar but differ from that of P.

---The lowest-energy absorption band of p consists of at least two separate electronic transitions. These are partially resolved in a non-polar solvent. By comparison with p-fluorobenzonitrile, the low-energy "tail" of the lowest-energy absorption band may be assigned as ${}^1L_b \leftarrow {}^1A$, while the intense part of this band is assigned as ${}^1L_a \leftarrow {}^1A$. The details of these transitions are presented in Table 2.

---The primary difference between the spectra of o and m and that of p is an increase in energy and decrease in intensity of the ${}^1L_b \leftarrow {}^1A$ band in p, along with a decrease in energy and increase in intensity of the ${}^1L_a \leftarrow {}^1A$ band of p.

---In o and m, fluorescence is structured and is the mirror image of the lowest-energy absorption band. The intrinsic emissive lifetimes obtained from the fluorescence data are 19 and 23ns for o and m, respectively. The same lifetimes, calculated from absorption data on the assumption that fluorescence is the inverse of the

lowest-energy absorption band, are 24 and 34ns, respectively. It is concluded that the fluorescence of o and m is $^1L_b \rightarrow ^1A$.

---For p, the situation is different (See Figure 5). The mirror image relationship now exists between the fluorescence and the low-energy "tail" of the lowest-energy absorption band. While the intrinsic emissive lifetime, obtained from fluorescence data is 32ns, that calculated from absorption data, assuming fluorescence to be the inverse of the whole lowest-energy absorption band, is ~2ns. This is clearly too low. The same lifetime, calculated by assuming that fluorescence is the inverse of the low-energy "tail" of the lowest-energy absorption band, is ~46ns. It is concluded that fluorescence is the inverse of the "tail" region of the lowest-energy absorption band and is $^1L_b \rightarrow ^1A$. Lifetimes and quantum yields are presented in Table 2.

---Phosphorescence is vibronically structured, indicating that the T_1 state is less polar than either the 1L_a or 1L_b states.

---The ϕ_P/ϕ_F ratio is largest for the p-isomer because of the smaller value of k_F for this isomer.

For further details on the cyanoanisoles, consult Lui and McGlynn³⁶.

3. CYANOANILINES: The polarity of the cyanoanilines, while moderate, exceeds that of the cyanoanisoles. The spectra of the OMP triad are given in Figures 6 and 7. The following general observations may be noted:

---The absorption spectra of o and m are similar and not much affected by an increase of solvent polarity. The absorption spectrum of p is distinct from that of o and m and is more sensitive to solvent

Figure 6.

The absorption spectra of o-, m-, and p-cyanoanilines in ethanol (solid line) and in 3-methylpentane (dashed line) at room temperature.

Figure 7.

polarity.

---The low-energy absorption band of p consists of at least two separate electronic transitions. These are partially resolved in non-polar solvents. In 3-methyl pentane (3MP), the lowest-energy band maximizes at $\sim 34,500\text{cm}^{-1}$ and consists primarily of ${}^1L_b \leftarrow {}^1A$. The band that maximizes at $38,000\text{cm}^{-1}$ corresponds to ${}^1L_a \leftarrow {}^1A$ and has an increased charge-transfer character (vide infra). Details are collected in Table 3.

---The primary differences between the spectra of o and m and that of p is a decrease in energy and increase in intensity of ${}^1L_a \leftarrow {}^1A$ in p and an increase in energy and decrease in intensity of ${}^1L_b \leftarrow {}^1A$ in p. Thus, in comparison to the weakly-polar p-fluorobenzonitrile, in which the ${}^1L_b \leftarrow {}^1A$ transition is still distinct, the ${}^1L_b \leftarrow {}^1A$ transition of p-cyanoaniline in a polar solvent is completely occluded by the ${}^1L_a \leftarrow {}^1A$ transition.

---As a result of the large charge-transfer character (See Computational Results) of the ${}^1L_a \leftarrow {}^1A$ transition of p, this transition is very sensitive to solvent polarity. Thus, the ${}^1L_a \leftarrow {}^1A$ transition of p exhibits a larger energy decrement on going from non-polar to polar solvent than does the ${}^1L_b \leftarrow {}^1A$ transition.

---The fluorescence spectra of o, m and p exhibit little or no vibronic structure (when compared to the fluorescence spectra of the weakly-polar fluorobenzonitriles and the moderately-polar cyanoanilines). In part, this may be attributable to the near degeneracy of the 1L_a and 1L_b states in the cyanoanilines but, more probably, it reflects the increased solvent-solute and solute-solute interactions in the more-polar cyanoanilines.

FOOTNOTE TO TABLE 3

^aAbsorption measurements were made at 298⁰ K; emission studies were made in ethanol at 77⁰ K. The experimental error is $\pm 50 \text{ cm}^{-1}$. The symbol ϵ denotes the extinction coefficient (in $\text{l mole}^{-1} \text{cm}^{-1}$) and f denotes the oscillator strength. The subscripts F and P denote fluorescence and phosphorescence, respectively.

^bThe absorption data used here refer to glassy ethanol solutions at 77⁰ K.

---The absorption and fluorescence spectra of p do not exhibit a mirror image relationship (See Figure 8). The vibronic intervals (800 and 1200cm^{-1}) which occur in the fluorescence spectrum, however, also appear in the low energy "tail" of the lowest-energy absorption band, and suggest that fluorescence is the inverse of the $^1L_b \leftarrow ^1A$ absorption. This conclusion is substantiated by the large half-width of the lowest-energy absorption band ($\sim 4500\text{cm}^{-1}$) relative to that of the fluorescence band ($\sim 3000\text{cm}^{-1}$). Finally, the intrinsic fluorescence lifetime calculated from the absorption data, assuming fluorescence to be the inverse of the low energy "tail", is $\sim 27\text{ns}$, and is in good agreement with the observed value of 33ns . In contrast, the intrinsic radiative lifetime calculated by assuming that fluorescence is the inverse of the entire lowest-energy band is $\sim 2\text{ns}$. The luminescence lifetimes and quantum yield data are given in Table 3.

---The diffuseness of the fluorescence spectra prohibits any mirror image correlations for o and m. Nonetheless, the half-widths of the fluorescence and the lowest-energy absorption ($^1L_b \leftarrow ^1A$) bands are almost identical ($\sim 3000\text{cm}^{-1}$). In addition, the intrinsic emissive lifetimes (22 and 15ns , respectively) agree well with those calculated from absorption data ($\sim 22\text{ns}$ in both cases) by assuming the fluorescence to be the inverse of the whole lowest-energy absorption band.

---The increased vibronic structure of the phosphorescence spectrum of p as compared to the fluorescence spectrum, indicates that the T_1 state is less-polar than the 1L_b state.

---As is the case for the fluorobenzonitriles and the cyanoanisoles, the Φ_P/Φ_F ratio is largest for p. Again, this is primarily attributed to a larger k_{ISC} and a smaller k_F for p than for either

Figure 8.

o or m. For further details, see Lui and McGlynn³⁷.

4. AMINOACETOPHENONES: The aminoacetophenones are relatively polar. Their spectra are given in Figures 9 and 10. The following results may be noted:

---The absorption spectra of o and m are quite similar but different from that of p.

---The lowest-energy absorption bands ($^1L_b \leftarrow ^1A$) of o and m are quite similar but different from that of p.

---The lowest-energy absorption bands ($^1L_b \leftarrow ^1A$) of o and m are structureless in ethanol and 3MP. The lowest-energy absorption band of p is much more intense than that of either o or m, and it is also structureless in ethanol solution. In 3MP solution, however, a weakly structured edge is observed on the low-energy "tail" of this band (Figure 9). This low-energy "tail" lies at $\sim 29,400\text{cm}^{-1}$ and is assigned as the $^1L_b \leftarrow ^1A$.

---Apart from the "tail" region, the lowest-energy absorption band in p maximizes at $35,090\text{cm}^{-1}$ in 3MP, and is assigned as the $^1L_a \leftarrow ^1A$ transition. On the basis of correlative arguments (vide infra), the $40,000\text{cm}^{-1}$ band of o and m is assigned as $^1L_g \leftarrow ^1A$.

---The $44,000\text{cm}^{-1}$ band in o and m and the $43,000\text{cm}^{-1}$ and $51,000\text{cm}^{-1}$ bands of p must be assigned to transitions other than 1L_g , $^1L_b \leftarrow ^1A$. These, presumably, involve π^* excited states of 1B_a and 1B_b symmetries. The details of the S_3 , 1L_a , $^1L_b \leftarrow ^1A$ transitions are collected in Table 4.

---o and m exhibit broad structureless fluorescences with a half-band-width of $\sim 4000\text{cm}^{-1}$. The half-band-width of the lowest-energy absorption is also $\sim 4000\text{cm}^{-1}$, and an approximate mirror image rela-

^aAbsorption measurements were made at 298⁰K; emission studies were made at 77°K. The experimental error is 50 cm⁻¹, ϵ is the molar decadic absorption coefficient and f is the oscillator strength. The subscripts P and F refer to phosphorescence and fluorescence, respectively.

tionship to fluorescence does exist in both cases. The intrinsic radiative lifetimes, from fluorescence data, are 20 and 38ns for o and m, respectively. The same lifetimes obtained from absorption data for the lowest-energy absorption band are 24 and 38ns, respectively. We conclude that the fluorescences of o and m are ${}^1L_b \rightarrow {}^1A$.

---Again, however, the situation is different for p (See Figure 11). The fluorescence is not a mirror image of the entire lowest-energy band of the 300°K absorption spectrum. It can, however, be viewed as the inverse of the low-energy "tail" of the lowest-energy absorption process. The intrinsic emissive lifetime, from the fluorescence data, is ~480ns. That calculated from absorption data, assuming that the fluorescence is the inverse of the entire lowest-energy band, is ~4ns. The same lifetime, calculated by assuming the fluorescence to be the inverse of the low-energy "tail" is ~1080ns. While this last value is deviant by a factor of two, we think this unimportant because of the indeterminacy involved in separating the "tail" region from the main portion of the lowest-energy band. One may conclude³⁸ that the lowest-energy absorption band consists of two electronic transitions, that only a small part of its oscillator strength is due to the ${}^1L_b \leftarrow {}^1A$ excitation, and that the majority of its oscillator strength is conferred by the ${}^1L_a \leftarrow {}^1A$ transition.

---Yamaguchi et al.³⁹, have reported the absorption spectrum of p in ethanol at 77°K. They find that there exists a good mirror image relationship between the entire lowest-energy absorption band and the fluorescence spectrum. The lowest-energy absorption band undergoes a red-shift upon decreasing the temperature to 77°K, and the low-energy "tail" is no longer observed. In non-polar solvents, fluorescence

Figure 11.

The fluorescence and absorption spectra of *p*-amino-acetophenone. The fluorescence refers to an ethanol glass at 77°K. The absorption refers to a 3-methyl-pentane solution at room temperature. The mirror plane position is indicated by a vertical line.

was found to be weak and to be observable only when the exciting wavelength was that of the low-energy absorption "tail". While phosphorescence is observed at 77°K, both in polar and in non-polar solvents, the excitation spectra for fluorescence and phosphorescence are not identical in either the polar or non-polar media. They also found that the phosphorescence excitation spectrum in non-polar solvent corresponds to the low-temperature absorption spectrum in non-polar solvent, while the fluorescence excitation spectrum in polar solvent bears some similarity to the low-temperature absorption spectrum in polar solvents. These authors assign the low-energy absorption "tail" as an $n \rightarrow \pi^*$ transition and the lowest-energy absorption band as $\pi \rightarrow \pi^*$. Their results are both surprizing and confusing. We will return to them later.

---A summary of emissive lifetimes and quantum yields is given in Table 4. The Φ_P/Φ_F ratio for p is ~10 times that of either o or m. The primary cause of this effect is that k_F for P is smaller than that for either o or m. The comparatively high-energy of the T_1 state of o and its low radiative lifetime is attributed to a sterically-induced non-planarity between the ring and the substituent systems. For further details, see Lui and McGlynn³⁸.

5. NITROANILINES: The nitroanilines are highly-polar. Their spectra are shown in Figures 12 and 13. The following general observations may be made:

---The absorption spectra of o and m are similar but differ greatly from that of p.

---The lowest-energy band is distinct in all three isomers while the higher-energy bands exhibit considerable overlapping.

Figure 12.

The absorption spectra of the nitroanilines: (a) in methylcyclohexane at room temperature and (b) in an EPA glass at 77°K.

Figure 13.

The corrected emission spectra of o-, m-, and p-nitro-anilines in EPA glass at 77^0K . The total emission of the p-isomer (dashed line) consists solely of phosphorescence, that of the o- (solid line) and m- (dotted line) derivatives consist solely of fluorescence.

---There is a general increase in structure, accompanied by significant band shifts, on going from a non-polar solvent at 300⁰K to a polar, glassy medium at 77⁰K. The lowest-energy absorption band undergoes the largest decrease in energy on going to a polar medium: o (2700cm⁻¹), m(3700cm⁻¹) and p(5200cm⁻¹). Data are collected in Table 5.

---The large solvent-induced red-shift of the lowest-energy absorption band of p uncovers a structured region with apparent origin at 33,000cm⁻¹. This region is relatively insensitive to solvent polarity or to the degree of N-methylation. A shoulder at 33,000cm⁻¹ has been detected previously by Tanaka^{40,41} in the crystal spectrum of p and assigned as $^1\Gamma_{n\pi^*} \leftarrow ^1\Gamma_1$. However, the intensity ($\epsilon \approx 1500 \text{ l mole}^{-1} \text{ cm}^{-1}$) of this transition, coupled with the absence of solvent effects, tends to discredit this assignment. It has been suggested by El-Aassar⁴² that this transition is $^1L_b \leftarrow ^1A$ in nature, and we tend to agree with this assignment (vide infra). However, since no polarization data exist, no rigorous discrimination between $^1\Gamma_{n\pi^*} \leftarrow ^1\Gamma_1$ or $^1\Gamma_{\pi\pi^*} \leftarrow ^1\Gamma_1$ assignments is feasible.

---Electrodichroic⁴³ and solvatochromic⁴⁴ studies indicate that the 31,000cm⁻¹ absorption band (non-polar solvent) of p consists of two electronic transitions; one of these is intense and long-axis polarized, while the other is weaker and short-axis polarized. A similar situation has been found⁴³ in the corresponding 28,000cm⁻¹ band of N,N-dimethyl-p-nitroaniline(NNDMPNA).

---The luminescence of the nitroanilines may be summarized as follows:

- (i) o and m fluoresce but do not phosphoresce,

TABLE 5

NITROANILINES^a

	33,000- 36,000	32,520	1,500
	41,000	40,000	2,500
	45,500	43,700	6,500

^aThe extinction coefficient is denoted ϵ and is cited in units of $\text{l mole}^{-1}\text{cm}^{-1}$; the oscillator strengths are denoted f; EPA spectra were run at 77°K; methylcyclohexane spectra were run at 300°K.

- (ii) \underline{p} phosphoresces but does not fluoresce in non-polar media.
- (iii) A fluorescence of \underline{p} is induced in polar media, and its intensity is enhanced by an increase of the solvent polarity.
- (iv) The quantum yield ratio, Φ_P/Φ_F , of \underline{p} depends, in certain polar media, on the excitation energy.

For further details, see Khalil *et al.*⁷

6. A SUMMARY OF SERIES A DATA: Certain trends are evident in the behavior of the five triad of Sections II.A.1-5. We now list these trends:

(i) As molecular dipolarity increases, the ${}^1L_a \leftarrow {}^1A$ absorption band of \underline{p} decreases drastically in energy and increases in intensity. The ${}^1L_b \leftarrow {}^1A$ absorption band of \underline{p} also decreases in energy, but less dramatically; and it also loses intensity. As a result, the ${}^1L_a - {}^1L_b$ band gap of \underline{p} , which may be as large as 12kK in a weakly-polar species, can even become negative (i.e., $E({}^1L_a) < E({}^1L_b)$) in a highly-polar species. Thus, $\Delta E({}^1L_a - {}^1L_b)$ decreases and $f({}^1L_a \leftarrow {}^1A)/f({}^1L_b \leftarrow {}^1A)$ increases with increasing molecular dipolarity.

(ii) In \underline{o} and \underline{m} , the ${}^1L_a \leftarrow {}^1A$ and ${}^1L_b \leftarrow {}^1A$ absorption bands are less sensitive to molecular dipolarity. In \underline{o} , the ${}^1L_a \leftarrow {}^1A$ energy decreases by $\sim 6000\text{cm}^{-1}$ on proceeding from a weakly- to a highly-polar molecule. However, the ${}^1L_b \leftarrow {}^1A$ energy appears to be a more sensitive function of the molecular dipolarity, with the result that $\Delta E({}^1L_a - {}^1L_b)$, which usually lies in the range 8-12kK, tends to increase slightly with increasing molecular dipolarity. $f({}^1L_a \leftarrow {}^1A)$ is erratic but does tend to increase; $f({}^1L_b \leftarrow {}^1A)$ exhibits a definite increase, with the result that $f({}^1L_a \leftarrow {}^1A)/f({}^1L_b \leftarrow {}^1A)$, which usually lies in the range 1-10, tends to decrease as the molecular dipolarity increases.

(iii) The behavior of \underline{m} is very similar to \underline{o} . Both the ${}^1L_a \leftarrow {}^1A$ and ${}^1L_b \leftarrow {}^1A$ energies decrease with increasing molecular dipolarity, the latter being the more sensitive. As a result, $\Delta E({}^1L_a - {}^1L_b)$, which usually lies in the range 9-10kK and whose behavior is somewhat erratic, tends to increase with increasing polarity. $f({}^1L_a \leftarrow {}^1A)$ either remains constant or decreases slightly; $f({}^1L_b \leftarrow {}^1A)$ exhibits a decided increase, with the result that $f({}^1L_a \leftarrow {}^1A)/f({}^1L_b \leftarrow {}^1A)$ ---which, where measureable, lies in the 2.5-8 range --- tends to decrease with increasing dipolarity.

(iv) Solvent effects are much greater in the more polar molecules and, within a given triad, for the *p*-isomer.

(v) In weakly-polar *p*, the ${}^1L_b \rightarrow {}^1A$ fluorescence process is more probable than the ${}^3L_a \rightarrow {}^1A$ phosphorescence. The inverse is true in highly-polar molecules. When the molecular polarity is so high that $\Delta E({}^1L_a - {}^1L_b) < 0$, a second reversal occurs and the luminescence is dominantly fluorescence (i.e., ${}^1L_a \rightarrow {}^1A$).

(vi) The behavior of Φ_P/Φ_F in \underline{o} and \underline{m} is erratic but it does exhibit a clear-cut tendency to decrease as the molecular polarity increases. The fluorescence and phosphorescence events can be described, in all instances, as ${}^1L_b \rightarrow {}^1A$ and ${}^3L_a \rightarrow {}^1A$, respectively.

These conclusions, while based on a good data set, suffer from the fact that this data set is small. We now attempt to verify these conclusions using a much larger but more qualitative data set.

B. SERIES B AND C.

1. *p*-ISOMERS:

The data set consists of Tables 1-5 as amplified by the more voluminous but less accurate data of Tables 6 and 7.

The p-amino series exemplifies a type B series: The amino group is held constant while the acceptor is varied. The absorption and emission energies for five such molecules are plotted in Figure 14, the molecules being arranged from left to right in order of increasing molecular polarity. It is obvious that the energetic characteristics of the 1L_a and 1L_b states agree with point (1) of our summary, Section III.A.6.

When the molecular polarity reaches that of p-aminobenzoic acid, the ${}^1L_a \leftarrow {}^1A$ and ${}^1L_b \leftarrow {}^1A$ bands have merged. At this point we assign the lowest-energy absorption band as ${}^1L_a \leftarrow {}^1A$ since this transition surely constitutes the dominant intensity component of the band. One must bear in mind, however, that the lowest-energy excited singlet state could still be the very weak ${}^1L_b \leftarrow {}^1A$ transition. Finally, when the polarity has increased to that of p-nitroaniline, fluorescence disappears entirely and phosphorescence dominates the luminescence spectrum.

The p-cyano series exemplifies a Type C series. Data for this series are diagrammed in Figure 15. The 1L_a state declines in energy more rapidly than does the 1L_b state; and the two bands merge when molecular polarity has reached that of the p-cyanophenoxide anion. The dominance of phosphorescence over fluorescence is not observed for this series, presumably because these molecules are not as polar as those of the p-amino series.

2. THE 1L_a RANKING CRITERION: The decline in energy of the ${}^1L_a \leftarrow {}^1A$ absorption band is assumed to arrange the p set of D- ϕ -A molecules according to increasing polarity. This ranking device is consistent with all the available data and it provides a simple, experimentally-

FOOTNOTES TO TABLE 7

^aAll energies refer to 77°K. Quoted energies are for 0,0 bands except where marked by "(m)" which connotes a band maximum. The experimental error is approximately 50 cm⁻¹. The ratio of phosphorescence to fluorescence intensities is denoted by ϕ_P/ϕ_F and has been corrected for instrument parameters. The absence of any symbolism in a given data slot indicates our inability to measure the quantity in question.

^bCompounds were purified by standard methods (distillation, crystallization, gas chromatography, volatilization and/or zone refining) until a constancy of luminescence parameters was achieved. All solvents were fluorometric grade and were non-emissive at the level of sensitivity needed in this work. Measurement procedures have been described elsewhere.³

^cMesomeric, inductive and steric effects are undoubtedly operative to some extent in all of these systems. It seems reasonable that the relative importance of these effects in the different isomers varies as follows:

o : steric; inductive ≥ mesomeric

m : inductive only

p : mesomeric ≥ inductive

The energies of S₁ and T₁ states will depend on that particular mix of these effects which operates in the given of a given molecule. For example, in the chloro- and bromobenzonitriles, m is of highest T₁ and S₁ energy, presumably because only the inductive effects operates in this isomer. In a "stronger" DA system, where p possesses the highest T₁ and S₁ energies, we must, it seems, associate this happenstance with a dominant importance of the mesomeric effect in these cases.

Figure 14.

The absorption and emission data for p-amino substituted benzenes. The absorption data refer to non-polar media (3-methylpentane or methylcyclohexane) at room temperature; the emission data refer to glassy ethanol or EPA solutions at 77°K. The circles refer to band origins, the squares refer to band maxima. The molecules are arranged in order of increasing molecular polarity as determined by decreasing ${}^1L_a \leftarrow {}^1A$ energy. The numbers are the experimental oscillator strengths of the transitions.

Figure 15.

The absorption and emission data for p-cyano substituted benzenes. The absorption data refer to non-polar media (methylcyclohexane or 5-methylpentane) at room temperature; the emission data refer to glassy ethanol or EPA solutions at 77⁰K. The squares refer to band maxima, the circles refer to band origins. The molecules are arranged in order of increasing molecular polarity as determined by decreasing $^1L_a \leftarrow ^1A$ energy. The numbers are the experimental oscillator strengths of the transitions.

direct method of comparing molecules with completely different substituents.

This ranking parameter also serves to arrange the o and m series according to polarity. In this latter case, however, it is less sensitive simply because the effect of molecular polarity on the ${}^1L_a \leftarrow {}^1A$ energies is not as large as in the p case.

This ranking device also possesses certain disadvantages. These are:

---The ${}^1L_a \leftarrow {}^1A$ origin is not usually observed. Therefore, the ${}^1L_a \leftarrow {}^1A$ band maximum is used. This maximum is usually broad (i.e., not sharp). Furthermore, the energy of this maximum changes markedly with solvent, temperature, and pressure---which may be both bothersome and advantageous.

---The ${}^1L_a \leftarrow {}^1A$ band envelope may contain more than one transition (e.g., nitroaniline and the N-methyl substituted nitroanilines). One may assume that the ${}^1L_a \leftarrow {}^1A$ transition dominates, but one cannot always be sure of this.

---Ideally, vapor-phase spectra should be used to obtain accurate ${}^1L_a \leftarrow {}^1A$ origins which are free of solvatochromic¹³ effects. Unfortunately, most highly-polar D- ϕ -A molecules have very low vapor pressures. Therefore, in order to reduce the error that may be caused by large solvatochromic effects, we use the ${}^1L_a \leftarrow {}^1A$ absorption data for non-polar solvents.

The absorption and emission data for 20 p-D- ϕ -A molecules arranged according to decreasing ${}^1L_a \leftarrow {}^1A$ energy are presented in Figure 16. The following trends may be discerned:

---The ${}^1L_a \leftarrow {}^1A$ band declines in energy faster than does the

Figure 16.

The absorption and emission data for *p*-disubstituted benzenes, arranged according to increasing molecular polarity as determined by decreasing $^1L_a \leftarrow ^1A$ energy. The absorption data refers to non-polar media (methylcyclohexane or 3-methylpentane) at room temperature; the emission data refers to glassy ethanol or EPA media at 77°K. The squares refer to band maxima, the circles to band origins. The molecules are numbered as follows: 1, *p*-fluorobenzonitrile; 2, *p*-toluamide; 3, *p*-chlorobenzonitrile; 4, *p*-cyanophenol; 5, *p*-bromobenzonitrile; 6, *p*-cyanoanisole; 7, *p*-methoxybenzoic acid; 8, *p*-cyanoaniline; 9, methyl *p*-aminobenzoate; 10, *p*-aminobenzoic acid; 11, N,N-dimethyl-*p*-aminobenzonitrile; 12, *p*-nitrophenol; 13, *p*-aminoacetophenone; 14, N-methyl-*p*-aminobenzoic acid; 15, N,N-dimethyl-*p*-aminobenzoic acid; 16, *p*-nitroaniline; 17, N-methyl-*p*-nitroaniline; and 18, N,N-dimethyl-*p*-nitroaniline.

$^1L_b \leftarrow ^1A$ band.

---When the energy of the $^1L_a \leftarrow ^1A$ band has decreased to that of N,N-dimethyl-*p*-cyanoaniline, the $^1L_b \leftarrow ^1A$ band is not observed (Figure 15).

---Fluorescence occurs from the 1L_b state in the less-polar molecules. As the 1L_a and 1L_b energy levels converge towards coincidence, however, fluorescence disappears. This is undoubtedly due to the decrease of the $^1L_b \leftarrow ^1A$ transition dipole moment---which is observed experimentally and expected theoretically⁴⁵---and to the expected increase of molecule-solvent non-radiative depletion routes which compete with the weak $^1L_b \rightarrow ^1A$ fluorescence pathway.

---Fluorescence re-emerges and becomes the dominant energy-depletion route when the 1L_a state drops energetically below the 1L_b state-- $^3L_a \rightarrow ^1A$ phosphorescence remains viable as the $^1L_b \rightarrow ^1A$ fluorescence efficiency decreases. However, when the $^1L_a \rightarrow ^1A$ fluorescence pathway becomes feasible, the $^3L_a \rightarrow ^1A$ phosphorescence tends to disappear.

We are now in a position to interpret the anomalous luminescence of *p*-aminoacetophenone (vide supra). We expect that the low-energy "tail" on the lowest-energy absorption band of *p*-aminoacetophenone in non-polar media is the $^1L_b \leftarrow ^1A$ transition. The weak fluorescence reported by Yamaguchi et al.³⁹ in non-polar media is then assigned as $^1L_b \rightarrow ^1A$. In polar media, however, the 1L_a level shifts to a lower energy than the 1L_b level and the fluorescence becomes $^1L_a \rightarrow ^1A$ in nature. The result is that the fluorescence and absorbance in polar media at 77°K are mirror images of one another whereas, in non-polar media, they are not. The fact that the fluorescence and phosphorescence excitation spectra are different can be explained³⁹ by invoking

coupling between the two excited singlet states. We agree on this, but disagree in that we assign the "tail" region as ${}^1\Gamma_{\pi\pi^*} \leftarrow {}^1\Gamma_1$ rather than ${}^1\Gamma_{\pi\pi^*} \leftarrow {}^1\Gamma_1$ as they do.

3. SOLVENT EFFECTS: In light of the above, we find it informative to view a polar D- ϕ -A molecule and its solvent cage as one distinct absorbing and emitting entity: A particular molecule embedded in two different solvent cages becomes, in effect, two different "molecules". Because the 1L_a state is more solvatochromic than is 1L_b , we can adjust the relative energies of these two states by a judicious choice of solvent. Hydrogen bonding effects⁴⁶, of course, are inherently included.

If the energy of the ${}^1L_a \leftarrow {}^1A$ band is used to arrange a series of these "molecule-solvent species", certain generalizations about fluorescence and phosphorescence may be noted. Such a series is presented in Figure 17. As the polarity of the system increases, fluorescence decreases and phosphorescence dominates. At the point where the 1L_a and 1L_b states are approximately isoenergetic, fluorescence disappears entirely. As polarity increases further, however, and as the 1L_a and 1L_b states invert, a fluorescence reappears. Finally, when the 1L_a state has decreased to that of NNDMPNA in polyvinyl alcohol (PVA), phosphorescence disappears and the ${}^1L_a \rightarrow {}^1A$ fluorescence dominates the emission spectrum.

4. o-ISOMERS: Since long- and short-axes cannot be defined for o and m, the (L_a , L_b)-notation is no longer rigorous. However, all of these isomers possess two low energy ${}^1\Gamma_{\pi\pi^*}$ states and these can be correlated (vide infra) with the 1L_b and the 1L_a states of benzene. In view of this, we designate the lowest-energy ${}^1\Gamma_{\pi\pi^*}$ state of the o- and p-isomers as " 1L_b " and the second lowest-energy ${}^1\Gamma_{\pi\pi^*}$

Figure 17.

The absorption and emission of a series of "molecule-solvent species," arranged according to decreasing ${}^1L_a \leftrightarrow {}^1A$ energy. The absorption and emission data were recorded in transparent media at $77^\circ K$.

state as " 1L_a ". Our use of this notation, then, should cause no confusion.

Data for the o-amino and o-cyano series are presented in Figures 18 and 19, respectively. The molecules are arranged from left to right according to increasing polarity. As is the case for the p-isomers, we see a general decrease in the energy of the $^1L_a \leftarrow ^1A$ and $^1L_b \leftarrow ^1A$ absorption bands as the molecular polarity increases. In addition, there is an overall increase in the oscillator strength of the $^1L_b \leftarrow ^1A$ band across the series, whereas that of the $^1L_a \leftarrow ^1A$ band tends to decrease. Fluorescence occurs from the 1L_b state in every case, while phosphorescence presumably always occurs from the 3L_a state. This latter assignment is substantiated to some extent by the fact that the $^1L_a - ^3L_a$ energy gap remains fairly constant across the series. Phosphorescence tends to decrease as the molecular polarity increases and, finally, in o-nitroaniline, where the intersystem crossing cannot compete with the efficient $^1L_b \rightarrow ^1A$ fluorescence pathway, it disappears altogether.

Because of the steady decrease of energy of the $^1L_a \leftarrow ^1A$ band with the molecular polarity, we re-adopt the ranking criterion of Figure 16 and 17. The result is shown in Figure 20, where the molecules are ordered from left to right according to decreasing energy of the $^1L_a \leftarrow ^1A$ band. The $^1L_b \leftarrow ^1A$ band does not converge on and meld into the $^1L_a \leftarrow ^1A$ band as in the p series. In fact, the $^1L_b \leftarrow ^1A$ band intensifies, becomes more distinct with increasing polarity and, if anything, diverges from the $^1L_a \leftarrow ^1A$ band. In addition, solvent effects on the $^1L_a \leftarrow ^1A$ and $^1L_b \leftarrow ^1A$ bands are quite small. We take these observations to mean that the dipolarity of o is less than that

Figure 18.

Absorption and emission data for o-substituted anilines, arranged according to molecular polarity as determined by the decrease in ${}^1L_a \leftarrow {}^1A$ energy. The absorption data refers to non-polar media (3-methylpentane or methylcyclohexane) at room temperature; the emission data refers to glassy ethanol or EPA media at 77°K. The circles refer to band origins, the squares refer to band maxima.

Figure 19.

Absorption and emission data for o-substituted benzonitriles, arranged according to increasing molecular polarity as determined by the decrease in the ${}^1L_a \leftarrow {}^1A$ energy. The absorption data refers to non-polar media (3-methylpentane or methylcyclohexane) at room temperature; the emission data refers to glassy ethanol or EPA media at 77°K. The circles refer to band origins, the squares refer to band maxima.

Figure 20.

The absorption and emission of o-disubstituted benzenes, arranged according to increasing molecular polarity as determined by decreasing $^1L_a \leftarrow ^1A$ energy. The absorption data refers to non-polar media (methylcyclohexane or 3-methylpentane) at room temperature; the emission data refers to glassy ethanol or EPA media at 77^0K . The circles refer to band origins, the squares refer to band maxima. The numbers are experimental oscillator strengths of the absorptive transitions.

of $P_{\text{---}}$ which it should be by a factor of ~ 2 . We also conclude, because of the lack of differential solvent shifts on the two bands, that the charge-transfer character of both the 1L_a and 1L_b states is essentially identical and, possibly, is even larger in the 1L_b state.

5. m-ISOMERS: The m-amino and m-cyano series are presented in Figures 21 and 22, respectively. The same general trends are exhibited as those found for the analogous series of the o-isomers. Figure 23 is generated by using the energy of the ${}^1L_a \leftarrow {}^1A$ band as the ranking device. From this correlation, we find that fluorescence always occurs from the 1L_b state, while phosphorescence is always presumed to arise from the 3L_a state.

C. OTHER EXPERIMENTAL OBSERVATIONS.

1. EMISSION POLARIZATION OF N,N-DIMETHYL-p-NITROANILINE (NNDMPNA):

The ${}^1L_a \rightarrow {}^1A$ and ${}^1L_b \rightarrow {}^1A$ transition moments of NNDMPNA are in-plane and mutually perpendicular, the former being directed along the long-axis and the latter along the short axis. The ${}^3L_a \rightarrow {}^1A$ transition moment, on the other hand, is expected⁴⁷ to be directed out-of-plane. Thus, fluorescence, whether ${}^1L_a \rightarrow {}^1A$ or ${}^1L_b \rightarrow {}^1A$, should possess a polarization direction which is perpendicular to that of phosphorescence³². This, as shown in Figure 24, is clearly the case.

Now, the majority of the intensity of the first absorption band is certainly ${}^1L_a \leftarrow {}^1A$. Thus, if the fluorescence is ${}^1L_b \rightarrow {}^1A$, it is expected that the fluorescence excitation spectrum will exhibit either total or nearly total negative polarization. It is obvious from Figure 24 that this is not so. The interpretation of the fluorescence excitation data requires that the fluorescence be ${}^1L_a \rightarrow {}^1A$ and that no significant part of the absorption intensity be either ${}^1L_b \leftarrow {}^1A$

Figure 21.

Absorption and emission data for m-substituted anilines, arranged according to molecular polarity as determined by the decrease in ${}^1L_a \leftrightarrow {}^1A$ energy. The absorption data refers to non-polar media (β -methylpentane or methylcyclohexane) at room temperature; the emission data refers to glassy ethanol or EPA media at 77°K. The circles refer to band origins; the squares refer to band maxima.

Figure 24.

The emission, emission polarization, excitation, and excitation polarization spectra of N,N-dimethyl-p-nitroaniline in EPA at 77°K, $\sim 10^{-5}$ M. P is the phosphorescence, F is the fluorescence, and TEP is the total emission polarization ($\lambda_{\text{excit}} = 380$ nm). FE is the fluorescence excitation, and FEP is the fluorescence excitation polarization ($\lambda_{\text{emit}} = 450$ nm). PE is the phosphorescence excitation and PEP is the phosphorescence excitation polarization ($\lambda_{\text{emit}} = 540$ nm). A is the absorption spectrum taken in EPA at 77°K. The emission spectrum is not corrected.

or ${}^1\Gamma_{n\pi^*} \leftarrow {}^1\Gamma_1$.

If any significant part of the absorption intensity is ${}^1\Gamma_{n\pi^*} \leftarrow {}^1\Gamma_1$, it is expected that the phosphorescence excitation spectrum will exhibit positive polarization. It is obvious from Figure 24 that this is not the case. Nonetheless, it is a fact that the phosphorescence excitation spectrum is least negative at larger λ and that the fluorescence and phosphorescence excitation spectra are not identical. Thus, somewhere in the vicinity of $410m\mu$, the vibrational deactivation cross-section within the singlet manifold becomes less than the cross-section for intersystem crossing to the triplet manifold. The most facile interpretation of this datum suggests the intrusion of ${}^{1,3}\Gamma_{n\pi^*}$ states in the $410m\mu$ region with the consequent enhancement of intersystem crossing via the processes ${}^1\Gamma_{n\pi^*} \rightsquigarrow {}^3\Gamma_{n\pi^*}$ and ${}^1\Gamma_{n\pi^*} \rightsquigarrow {}^3\Gamma_{n\pi^*} \rightsquigarrow {}^3\Gamma_{\pi\pi^*}$. The intrusion of such states in the $410m\mu$ region may also provide a rationale --- weak because of intensity considerations --- for the lesser negativity of phosphorescence polarization in the $410m\mu$ region.

Consequently, we may conclude the following:

---Phosphorescence is either ${}^3L_a \rightarrow {}^1A$ or ${}^3L_b \rightarrow {}^1A$. It is not ${}^3\Gamma_{n\pi^*} \rightarrow {}^1\Gamma_1$.

---Fluorescence is ${}^1L_a \rightarrow {}^1A$.

---The majority intensity of the lowest-energy absorption band is ${}^1L_a \leftarrow {}^1A$.

--- ${}^{1,3}\Gamma_{n\pi^*}$ states may well intrude in the $410m\mu$ region. It is well to note that a different interpretation of the disparity between phosphorescence and fluorescence excitation spectra --- one which does not invoke the intrusion of ${}^{1,3}\Gamma_{n\pi^*}$ states and which does not take account of the polarization data --- is available in the literature⁷.

2. THE CHARGE-TRANSFER BAND: The concept of a charge-transfer (CT) band in $D-\phi-A$ molecules has been promoted theoretically⁴⁸⁻⁵². The evolution of this concept gave rise to the supposition that a new transition of the type $D-\phi-A \xrightarrow{h\nu} D^+-\phi-A^-$ (or $D^+-\phi^-A$, or even $D-\phi^+-A^-$) should appear in the absorption spectrum^{48,53,54}. This charge transfer (CT) transition was expected to be long-axis polarized and quite intense⁴⁸, to exhibit large solvent effects⁵⁵⁻⁶⁰, and to produce a large static excited-state dipole moment directed along the substituent (long-) axis^{57,61}. Correlations with Hammett σ -constants⁶²⁻⁶⁸ with charge-transfer intensities, and with the steric effects of substituents^{49,69,70} have been investigated.

The interpretation of the electronic absorption spectroscopy of the $D-\phi-A$ molecules investigated here does not, in our opinion, require the proposition of a separate CT transition. The regular decrease of the 1L_a energy of the p set of $D-\phi-A$ molecules, which occurs as the molecular polarity increases, indicated an increasing perturbation of the 1L_a state by the substituents. This perturbation is consistent with the supposition that the ${}^1L_a \leftarrow {}^1A$ transition of the p set acquires an increasing degree of charge-transfer nature. It is this charge-transfer component which accounts for the observed trends in solvent shifts, excited state dipole moments, etc.

Thus, while we do not expect a CT transition to intrude at lower energies, the 1L_a and 1L_b states of o and m will also acquire increasing CT nature as the $D-o-A$ polarity increases.

We will discuss this point in considerable detail in the computational section.

3. THE TRIPLET STATE: The emissive triplet state is consistently

assigned as 3L_a (p-isomer) and as 3L_a -related (o- and m-isomers). The phosphorescence lifetimes are always of the order of 1 second, indicating surely a $^1\Gamma_{\pi\pi^*} \rightarrow ^1\Gamma_1$ transition. The evidence for the 3L_a assignment is based 1), on a correlation of the spectral characteristics of the T_1 state of these molecules with the T_1 state (3L_a)⁷⁰ of benzene and 2), on CNDO/s calculations (vide infra).

The singlet-triplet interval ($E_{^1L_a} - E_{^3L_a}$) of the p-isomers are shown in Table 8. They decrease regularly as the molecules become more polar. There are two primary reasons for this decrease: Firstly, since the more polar substituents tend to be bulkier, the molecular size tends to increase with increasing polarity. Consequently, the pertinent exchange integrals grow smaller and the S_1-T_1 interval decreases⁴⁷. Secondly, the extent of charge transfer increases with increasing polarity and this, as is well known⁴⁷, leads to a drastic reduction in the magnitude of the relevant exchange integrals. In fact, if the 3L_a state were 100% CT, the 1L_a and 3L_a states would be approximately degenerate.

The 1L_a state of D- ϕ -A molecules is quite polar (e.g., in NNDMPNA, $\mu(^1L_a) = 15D$ ⁷¹). The 3L_a state is less polar than the 1L_a state: Considerable structure is usually observed in the phosphorescence spectra but not in the fluorescence spectra of these molecules. It is known that $\mu(^1L_a)$ is long-axis oriented⁵⁷⁻⁶¹, as is $\mu(S_0)$. If one assumes that $\mu(T_1)$ is similarly aligned, then the T_1 state will also be solvent-stabilized by the ground state solvent cage. In support of this, it is observed that the T_1 state experiences little geometry change relative to the ground state; the phosphorescence origin is always prominent and is often the most intense peak, indicating a

TABLE 8

^aAll measurements were made in ethanol at 77°K.^bThe measurements refer to an DPA glass at 77°K.

favorable Franck-Condon geometric match with the ground state.

The above discussion assumed the existence of a rigid matrix in which no solvent-solute reorganization could occur. It is of note that Yamaguchi et al.⁶, have shown that the phosphorescence of p-aminoacetophenone in a rigid matrix (ethanol glass, 77°K) exhibits a prominent (0,0) band which, when warmed to 150°K to allow solvent reorganization to occur, experiences a red-shift (1700cm^{-1}) but remains equally prominent. This shift reflects the increased solvent sensitivity of the T_1 state and suggests that $\mu(T_1) > \mu(S_0)$.

4. DIPOLE MOMENTS AND SOLVENT EFFECTS: As discussed previously, $\mu(^1L_a)$ of the p D-Q-A sub-set is parallel to, but larger than $\mu(^1A_1)$. Since neither the solvent nor the solute may rearrange during the course of an electronic transition⁷¹, solvent stabilization should be larger⁷² for 1L_a than for 1A_1 . Thus, a red-shift of the $^1L_a \leftarrow ^1A$ band (i.e., a solvatochromism) is expected in polar solvents⁴⁴, and the degree of solvatochromism is expected to be proportional to the static dipole moment change which occurs upon excitation (i.e., to $|\mu(^1L_a) - \mu(^1A_1)|$)^{46,61}. This latter quantity has been adopted by Saidov et al.^{66,67} as a criterion for CT transitions.

In view of prior discussions, we conclude that a correlation between the 1L_a energy and the degree of solvatochromism is expected. The extent to which such a relationship exists is shown in Figure 25 and is not impressive. Nonetheless, if factors which inhibit the expected relationship are taken into account, most of the deviations may be rationalized. These factors are:

---Solvatochromism is less for alkyl-amino substituted aromatics than for amino substituted aromatics even though the former substi-

Figure 25.

Comparison of solvent shifts and ground state experimental dipole moments of *p*-disubstituted benzenes. The solvent shifts are calculated from the formula ($\tilde{\nu}[3mp] - \tilde{\nu}[EtOH]$) for the ${}^1L_a \leftarrow {}^1A$ band maximum at room temperature, except for *p*-tolunitrobenzene. For the latter molecule, the solvents are ethanol and hexane (taken from reference 60). The dipole moments are from reference 74.

tients are known to have the greater electron donating capacity. This deviation may be ascribed to hydrogen bonding⁴⁶, to methyl-amino group rotations, and to molecular size^{55,61}.

A reduction of temperature ($300^{\circ} \rightarrow 77^{\circ}\text{K}$) causes a red-shift of the ${}^1\text{L}_a \leftarrow {}^1\text{A}$ band that is similar to the shift caused by changing from non-polar to polar solvent (e.g., for NNDMPNA, the two shifts are 2500cm^{-1} and 2000cm^{-1} , respectively). This shift is probably due to the reduction of the Onsager radius as the density increases⁴⁵. In general, solvatochromism in both absorption and emission at 77°K is less than at 300°K (See Table 9). Since neither the ${}^1\text{L}_b$ nor the ${}^3\text{L}_a$ states are likely to be as polar as the ${}^1\text{L}_a$ state⁴, they exhibit smaller solvatochromic effects.

5. TEMPERATURE DEPENDENCE: Highly-polar molecules in non-polar solvents are known to dimerize in the ground state, affecting both absorption and emission^{37,73}. For example, the absorption spectra of p-cyanoaniline at various temperatures are presented in Figure 26. The lowest-energy absorption band is assumed to be due to the self-complex. Molecules in non-polar solvents at very low concentrations ($<10^{-5}\text{M}$) do not ordinarily exhibit dimerization phenomena in the absorption spectra but such effects do appear in the emission spectroscopy.

6. EXCITATION PHENOMENA: In many D- ϕ -A molecules, excitation into the extreme red edge of the lowest-energy absorption band results in a red-shift ($\sim 100\text{cm}^{-1}$) of the phosphorescence spectrum. Apparently, the molecules being excited are those whose triplet states are more efficiently solvated and, hence, are lower in energy⁴⁵.

7. LUMINESCENCE OF PARA D- ϕ -NO₂ COMPOUNDS: The luminescence properties of the nitroaromatics have long been a puzzle and the subject of considerable discussion^{60, 75-80}. Hence, it may be well to summarize that which is definitely known about these compounds:

---They possess a low-energy $^1\Gamma_{\pi\pi^*}$ state. This state, for example, is the S₁ state of nitrobenzene^{60,77} and 1-nitronaphthalene⁷⁸. As the strength of the donor substituent in D- ϕ -NO₂ is increased, the $^1\Gamma_{\pi\pi^*}$ energy will either increase slightly or remain constant.

---The T₁ state of 1-nitronaphthalene^{82,83}, possibly that of nitrobenzene⁷⁹, and all D- ϕ -NO₂ species where D is at least as strong as -OH is $^3\Gamma_{\pi\pi^*}$. This conclusion is fully justified by the observed phosphorescence lifetimes of Table 10. The intermediacy of D- ϕ -NO₂ phosphorescence lifetimes between that of a typical $^3\Gamma_{\pi\pi^*}$ state (benzene) and a typical $^3\Gamma_{\pi\pi^*}$ state (benzaldehyde) vindicates⁸⁴ the $^3\Gamma_{\pi\pi^*}$ nature of T₁ states in question and the presence of an adjacent $^1\Gamma_{\pi\pi^*}$ state (See previous item). The same conclusion follows by comparison with the substituted benzaldehydes of Table 10. As the donor strength of D increases, the energy of this T₁ state (i.e., $^3\Gamma_{\pi\pi^*}$ or L_a) will decrease.

---The lowest $^1\Gamma_{\pi\pi^*}$ state when D is a weak donor is 1L_b ; that, when D is a strong donor, is 1L_a . Both of these states decrease energetically as the donor strength increases, that of 1L_a being greatest. It follows, as donor strengths increase, that one may sample the energy sequences: $E(^1\Gamma_{\pi\pi^*}) < E(^1L_b) < E(^1L_a)$; $E(^1L_b) < E(^1\Gamma_{\pi\pi^*}) < E(^1L_a)$; $E(^1L_b) < E(^1L_a) < E(^1\Gamma_{\pi\pi^*})$; or $E(^1L_a) < E(^1L_b) < ^1\Gamma_{\pi\pi^*}$.

---The lowest-energy absorption band of D- ϕ -NO₂ entities, D being

a relatively good donor, encompasses all four transitions: $^1L_a \leftarrow ^1A$, $^1L_b \leftarrow ^1A$, $^1\Gamma_{n\pi^*} \leftarrow ^1\Gamma_1$, and $^3\Gamma_{n\pi^*} \leftarrow ^1\Gamma_1$. It is this proximity of nearly degenerate states which is responsible for the differences in fluorescence and phosphorescence excitation spectra (See Section C.1), and for the gross effects of solvent polarity and seemingly-innocuous chemical substitution (i.e., N-methylation) on the luminescence characteristics.

---The non-radiative intersystem crossing cross-sections $^1\Gamma_{n\pi^*} \rightsquigarrow ^3\Gamma_{n\pi^*}$ or $^1\Gamma_{n\pi^*} \rightsquigarrow ^3\Gamma_{n\pi^*}$ are much more efficient⁸⁰ than the routes $^1\Gamma_{n\pi^*} \rightsquigarrow ^3\Gamma_{n\pi^*}$ or $^1\Gamma_{n\pi^*} \rightsquigarrow ^3\Gamma_{n\pi^*}$. It is this fact which underlies the expectations of the previous item.

---The radiative cross-sections, as estimated from typical oscillator strength data, are $\sigma(^1\Gamma_{n\pi^*} \rightarrow ^1\Gamma_1) \approx 10^2(^1L_b \rightarrow ^1A) \approx 10(^1L_a \rightarrow ^1A)$.

We are now in a position to rationalize the gamut of observed luminescence behavior. Such a rationalization is schematized in Figure 27 and systems exemplifying the expected behavior are specified.

8. LUMINESCENCE OF ORTHO AND META D- ϕ -NO₂ COMPOUNDS: The lumines-

cence of these compounds, D being a strong donor, consists solely of fluorescence. The reasons for this are three-fold: Firstly, the $^1L_b \leftarrow ^1A$ band is intense in these systems, with the result that the $^1L_b \rightarrow ^1A$ cross-section is large. Secondly, the $^1\Gamma_{n\pi^*} \leftarrow ^1\Gamma_1$ transition is expected to lie at higher energies as one progresses through a given series $p \rightarrow m \rightarrow o$. Thirdly, the $^1L_b \leftarrow ^1A$ transition is expected to lie at lower energies in o and m than in p . Consequently, it is expected that $^1,^3\Gamma_{n\pi^*}$ states lie at higher energy than 1L_b . Hence,

Figure 27.

The excited states of *p*-substituted nitrobenzenes. The molecular polarity increases from left to right. In each of the four systems, the states on the left are singlet states and the states on the right are triplet states. The a refers to L_a , the b refers to L_b , and the n refers to the n, π^* state. Unsubstituted nitrobenzene or nitrobenzene with weakly polar substituents exhibits weak or no emission. More polar nitrobenzenes such as *p*-nitrophenol phosphoresce but have weak or absent fluorescence. Highly-polar nitrobenzenes such as *p*-nitroaniline and its methylated derivatives both phosphoresce and fluoresce. The intensities of phosphorescence and fluorescence are substituent and solvent dependent: in the very polar solvent polyvinylalcohol (PVA), only fluorescence is observed.

we expect little intersystem crossing (i.e., weak or no phosphorescence) and an efficient $^1L_b \rightarrow ^1A$ emissive path (i.e., fluorescence).

IV. QUANTUM CHEMICAL COMPUTATIONAL METHODS

All valence-electron, CNDO/s-CI computations, DelBene-Jaffé formalism^{85,86}, were performed on an IBM 360/65 computer using QCPE program CNDO 174. The Mataga-Nishimoto approximation⁸⁷ for two-center repulsion integrals was used. Convergence criteria and iteration procedures were those of King and Van Putten⁸⁸. Convergence occurred after eleven iterations in all cases except p-fluorobenzonitrile and p-aminobenzoic acid, which needed fifteen and twenty-five, respectively. The parametrizations for C, H, N and O proposed by Del Bene and Jaffé⁸⁵ and that proposed for F by Kuehnlenz and Jaffé⁸⁹ were used. Only the first thirty mono-excited configurations were included in the CI procedure.

Benzene was considered to be the parent molecule. The xz-plane is the molecular plane, the z-axis bisects \angle CCC, the y-axis bisects C-C bonds, and the coordinate origin lies on the inversion center. Standard bond lengths and bond angles were used⁹⁰.

The coordinate systems, point groups and structural references for all other molecules are presented in Figure 28 and Table 11. A C_s representation was considered adequate for molecules #9 and #10.

Any charge-transfer nature of an electronic transition is assumed to cause a movement of electron density from the vicinity of the donor substituent to the vicinity of the acceptor substituent. The amount of electron density lost by the donor in the transition $2 \leftarrow 1$ may be expressed, in the absence of CI as

Figure 28.

Geometries and axes for D- ϕ -A molecules. Point groups, index numbering and structural references are compiled in Table 11.

a) Perpendicular: The (N,C,C)-plane of the dimethylamino group is to the benzenoid plane.
 Parallel: The (N,C,C)-plane of the dimethylamino group is coplanar with that of the benzene group.

$$F_D = (\sum_i c_i^2)_{D,1} - (\sum_i c_i^2)_{D,2}$$

$$= X_{D1} - X_{D2}$$

where $(c_i)_{D,1}$ is the LCAO coefficient of the i th AO of one of the donor atoms in MO #1, and the sum is effected over all AO's of all centers of the donor group in MO #1. Hence, we can define X_{D1} and X_{D2} as electron density of the donor in states 1 and 2, respectively. The concept is readily extensible to the CI situation where states 1 and 2 are multi-configurational in nature.

The electron density gained by the acceptor substituent in the transition $2 \leftarrow 1$ is expressed as

$$F_A = (\sum_i c_i^2)_{A,2} - (\sum_i c_i^2)_{A,1}$$

$$= X_{A2} - X_{A1}$$

Consequently, the quantity $(F_A + F_D)$ constitutes a measure of the charge transfer character of the transition $2 \leftarrow 1$. The quantity $F_A + F_D$, as defined, is always positive -- at least to the extent that A and D behave as bona fide electron acceptors and donors, respectively.

The ground state dipole moments, μ_0 , were obtained using the Point-Charge Model^{102,103}:

$$\mu_0 = 4.8033 \sum_A Q_A \vec{r}_A \text{ (Debyes)}$$

where Q_A is the ground state charge density on center A and \vec{r}_A is the radius vector from the coordinate origin to center A.

V. COMPUTATIONAL RESULTS

A. p-ISOMERS

1. SINGLET STATES: The energies, oscillator strengths and transition moment vectors (i.e., polarizations) of the lower-energy singlet electronic states of the psubset are presented in Table 12. The following observations may be made:

---In all cases, except planar NNDMPNA, the lowest-energy $^1\Gamma_{\pi\pi^*}$ state is 1L_b , while the second lowest-energy $^1\Gamma_{\pi\pi^*}$ state is 1L_a . In the case of NNDMPNA, these two states are inverted.

---In molecules containing a cyano group, there are two states which normally lie energetically between the 1L_b and 1L_a states. These corresponding transitions are denoted $\pi(\text{CN}) \rightarrow \pi^*$ and $\pi \rightarrow \pi^*(\text{CN})$. We define a $\pi(\text{CN})$ orbital as an MO with > 50% of its electron density localized on the CN group in an in-plane π -bonding configuration (e.g., in p-fluorobenzonitrile, the $\pi(\text{CN})$ orbital has 25% of its electron density on the cyano carbon p_x AO and 48% on the nitrogen p_x AO). The two geometric isomers of N,N-dimethyl-p-cyanoaniline (NNDMPCA) exhibit additional $^1\Gamma_{\pi(\text{CN})\pi^*}$ states which lie energetically above the manifold of $^1\Gamma_{\pi\pi^*}$ states.

---The third and fourth $^1\Gamma_{\pi\pi^*}$ states in molecules of low polarity (e.g., p-fluorobenzonitrile) are related to the 1B states of benzene. However, as molecular polarity increases, a number of higher lying $^1\Gamma_{\pi\pi^*}$ states are pushed into the energy range of the 1L_b , 1L_a , 1B_b and 1B_a states.

---In p-aminobenzoic acid, the lowest-energy states is $^1\Gamma_{n\pi^*}$, the non-bonding electron density being localized on the carbonyl oxygen. In p-nitroaniline and the two NNDMPNA isomers, the lowest-

TABLE 12

energy excited states are $^1\Gamma_{n\pi^*}$, the non-bonding electron density now being localized on the oxygens of the NO_2 group. Two low-energy $^1\Gamma_{n\pi^*}$ states -- the n MO being largely a $2p_x$ AO localized on the amino nitrogen -- occur also in NNDMPCA but, in this case, they are not computed to be the lowest-energy excited states.

---In all molecules containing a nitro group, states whose orbital promotions initiate in MO's localized on out-of-plane (p_y) oxygen AO's and terminate in π^* MO's are computed to be of low energy. These promotions are denoted $l \rightarrow \pi^*$ (l = lone pair) and are of the same symmetry as certain $^1\Gamma_{\pi\pi^*}$ states.

---The highest-energy states in all *p*-isomers listed result from $\sigma \rightarrow \pi^*$ promotions.

---Similar calculations have been performed on several molecules of Table 17 (*p*-cyanophenol, *p*-cyanoaniline and the two geometric isomers of NNDMPCA) by Khalil *et al.*¹¹ All states other than $^1\Gamma_{\pi\pi^*}$ states were mistakenly assigned by these authors as $\sigma \rightarrow \pi^*$ promotions.

2. TRIPLET STATES: The energies of the computed triplet states of the *p*-sub-set are presented in Table 13. The following observations are pertinent.

---In every case, except benzene and *p*-nitroaniline, the lowest-energy $^3\Gamma_{\pi\pi^*}$ state is 3L_a while the second-lowest energy $^3\Gamma_{\pi\pi^*}$ state is 3L_b . This result holds even for planar NNDMPNA in which the 1L_b and 1L_a states have been inverted. In benzene, the first and the third $^3\Gamma_{\pi\pi^*}$ states derive from L_a and L_b configurations, respectively, whereas the second $^3\Gamma_{\pi\pi^*}$ state (a degenerate state) derives from an E_{1u} configuration (B_a, B_b). The third $^3\Gamma_{\pi\pi^*}$ state of *p*-nitroaniline is 3L_b whereas both the first and second $^3\Gamma_{\pi\pi^*}$ states contain a consid-

erable L_a configurational component.

---The lowest-energy triplet state of molecules which contain an NO_2 group is of ${}^3\Gamma_{\ell,\pi\pi^*}$ nature. Indeed, all molecules which have ${}^1\Gamma_{n\pi\pi^*}$ states at energies $\leq 5.4\text{eV}$ have energetically-identical ${}^3\Gamma_{n\pi\pi^*}$ states which, perforce, are included in Table 13. This singlet-triplet degeneracy also holds for ${}^{1,3}\Gamma_{\pi(\text{CN})\pi\pi^*}$, ${}^{1,3}\Gamma_{\pi\pi\pi^*(\text{CN})}$ and ${}^{1,3}\Gamma_{\sigma\pi\pi^*}$ states and is a consequence of the approximations inherent in the CNDO formalism¹⁰⁴.

3. DIPOLE MOMENTS: The computed values of the ground state dipole moment, μ_0 , are collected in Table 14 and compared with the experimental values.

The ${}^1\Gamma_{\pi\pi\pi^*}$ states of the \underline{p} sub-set, arranged from left to right in order of increasing $|\mu_0|$, are correlated in Figure 29. From reference to Figure 29 and, following the order in which molecular polarity increases, one concludes that:

---The ${}^1L_a - {}^1L_b$ energy gap decreases.

---The ${}^1L_a \leftarrow {}^1A$ absorption band decreases in energy to a greater extent than does the ${}^1L_b \leftarrow {}^1A$ absorption band.

---There is an overall intensity increase in the ${}^1L_a \leftarrow {}^1A$ absorption band.

---The ${}^1B_a - {}^1B_b$ energy gap increases.

---When the molecular polarity is very large (e.g., planar NNDMPNA), the 1L_a and 1L_b states invert order.

---The ${}^1L_a - {}^3L_a$ interval decreases. This observation, of course, is not intrinsic to Figure 29 but is validated by the data of Table 15.

In order to test the experimental supposition that a decreasing

a) μ_0 is calculated by the point-charge approximation using charge densities taken from CNDO/S computations.

b) All experimental values are from Reference 74. In every case the dipole moment values are from measurement of the dielectric constant (benzene solvent, 25°C).

c) The numbering of molecules refers to Table 11.

d) The percentage of electronic polarization used for atomic polarization in the calculation of dipole moment from dielectric constant data is zero for benzene and molecules 8, 14; five for molecules 2, 5, 9 (average of two values), 10, 11, 17; and fifteen for molecule 3. A "dash" in this column indicates that the value was not reported. No values are listed for molecules 4 and 7, since they are the perpendicular isomers of 3 and 6.

Figure 29.

Correlation of ${}^1\Gamma_{\pi\pi^*}$ (CNDO/s-C.I.) states of *p*-disubstituted molecules with the ${}^1\Gamma_{\pi\pi^*}$ state of benzene. The molecules are arranged from left to right in order of increasing computed ground state dipole moment, $|\mu_0|$. The molecules are denoted as follows: A, benzene; B, *p*-fluorobenzonitrile; C, *p*-cyano-phenol; D, *p*-aminoacetophenone; E, N,N-dimethyl-*p*-cyanoaniline (nonplanar); F, *p*-aminobenzoic acid; G, *p*-cyanoanisole; H, *p*-cyanoaniline; I, N,N-dimethyl-*p*-cyanoaniline; J, N,N-dimethyl-*p*-nitroaniline (non-planar); K, *p*-nitroaniline; and L, N,N-dimethyl-*p*-nitroaniline.

TABLE 15
COMPUTED (CNDO/s-CI) 1L_a - 3L_a ENERGY SPLIT

p-dimethylaminobenzonitrile, planar a)	2.158
p-dimethylaminobenzonitrile, perpendicular a)	2.526
p-aminobenzoic acid	2.394
p-nitroaniline	1.930
N ₁ N-dimethyl-p-nitroaniline, planar a)	1.676
N ₁ N-dimethyl-p-nitroaniline, perpendicular a)	2.061

o-hydroxybenzonitrile	2.531
o-aminobenzonitrile	2.378
o-nitroaniline	2.139

m-hydroxybenzonitrile	2.600
m-aminobenzonitrile	2.469
m-nitroaniline	2.421

energy of the ${}^1L_a \leftarrow {}^1A$ absorption band implies an increasing molecular polarity, we have re-ranked the molecules of Figure 29 --- the perpendicular geometric isomers of both NNDMPCA and NNDMPNA being omitted --- according to decreasing experimental energy of the ${}^1L_a \leftarrow {}^1A$ band. The resulting correlation is presented in Figure 30. Even though three molecules in the medium polarity range (i.e., p-cyano-phenol, p-cyanoaniline and p-aminoacetophenone) are shifted relative to their ranking in Figure 29, the overall experimental trends of Section III, and the trends evidenced in Figure 29 are reproduced.

4. CHARGE TRANSFER: The charge transfer nature of the 1L_a state is analyzed in terms of the quantity $F_A + F_D$ in Figure 31. The quantity $F_A + F_D$, for both the 1L_a and 1L_b states, is plotted versus the computed 1L_a energy. The six molecules considered cover the range from relatively non-polar to highly-polar. It is clear that, as molecular polarity increases, the CT nature of both states increases, that of the 1L_a state being by far the more sensitive. Over the same polarity range, the 1L_b state exhibits an increase in CT character that is less than half that exhibited by the 1L_a state.

In specific, it may be said that the 1L_a state of NNDMPNA is 68% charge transfer in nature, and that the 1L_a states of PNA is 50% CT. In this sense, it is not illogical to rename the 1L_a state of NNDMPNA the "CT State". But it is presumptuous to extend this terminology to the 1L_a states of NNDMPCA, PCA, PCP, or, indeed, to any molecule which lies leftward of PNA in Figure 31. By the same token, it may well be equally presumptuous of us to use the name 1L_a for that excited state of NNDMPNA which is mostly (i.e., 68%) CT.

The truth of the matter is that the choice of name is irrelevant

Figure 30.

Correlation of ${}^1\Gamma_{\pi\pi^*}$ (CNDO/s-C.I.) states of p-disubstituted molecules with the ${}^1\Gamma_{\pi\pi^*}$ states of benzene. The molecules are arranged from left to right in order of decreasing experimental ${}^1L_a \leftrightarrow {}^1A$ energy. The molecules are denoted by the following: A, benzene; B, p-fluorobenzonitrile; C, p-cyanophenol; D, p-cyanoanisole; E, p-cyanoaniline; F, p-aminobenzoic acid; G, N,N-dimethyl-p-cyanoaniline; H, p-aminoacetophenone; I, p-nitroaniline; and J, N,N-dimethyl-p-nitroaniline.

Figure 31.

Total charge transferred, as measured by the quantity $F_a + F_b$, in the ${}^1L_a \leftarrow {}^1A$ transition (open circles) and the ${}^1L_b \leftarrow {}^1A$ transition (closed circles) of p-disubstituted benzenes. The molecules are denoted as follows: A refers to p-fluorobenzonitrile; B, p-cyanophenol; C, p-cyanoaniline; D, N,N-dimethyl-p-cyanoaniline; E, p-nitroaniline; and F, N,N-dimethyl-p-nitroaniline.

as long as one understands what that name means. The name "CT" refers the state to a zeroth-order description where one obtains total charge separation (i.e., $D^+-\phi-A^-$ or 100% electron transfer). It may well be the description of choice for the individual whose interests reside mostly in solvent effects. We prefer the name 1L_a simply because this state correlates back in a smooth way to benzene, no abrupt change or behavioral alteration being noticeable at any point. The difficulty resides in the subtle differences that different names imply for different people. Thus, should the attribution CT imply the presence of a 1L_a state somewhere nearby? We think not. Yet, this is precisely the implication extracted by certain authors.

Thus, for precision, we emphasize: The name 1L_a is preferable since it does not preclude a specifiable, large or small, CT character; since it refers to a readily accessible zeroth-order state, say that of $p-F-\phi-CN$ or even benzene; and since the progression from the zeroth-order point to the molecule of interest is readily traversed empirically, using any of the experimental trends noted in this work.

5. TRANSITION INTENSITIES: In the p sub-set, a hypothetical intramolecular CT transition which causes a migration of charge from the donor to the acceptor will be long-axis polarized. It is also expected to be intense. The $^1L_a \leftarrow ^1A$ transition is also long-axis polarized and may obtain intensity by configuration mixing with the CT state. The $^1L_b \leftarrow ^1A$ transition is short-axis polarized and may not obtain intensity in this fashion. Hence, presuming that the hypothetical CT transition is, in fact, intense and that there is considerable $^1L_a/^1CT$ mixing, we expect the nominal $^1L_a \leftarrow ^1A$ transition to increase in intensity as molecular polarity increases. This is also the case

experimentally. However, it is not the case theoretically. The computed values remain rather constant at $0.2 < f \leq 0.35$ and, while larger than $f(^1L_b \leftarrow ^1A)$ by a factor ranging from 10 to 10^2 , they exhibit no discernible trend.

B. o-Isomers

The computed energies, oscillator strengths and transition dipole moment vectors of the singlet electronic states of the ortho-disubstituted molecules are given in Table 16. Since long- and short-axes cannot be uniquely defined for these molecules, the (L_a, L_b) -notation is meaningless. As in the case of the experimental data, however, we have found that certain $^1\Gamma_{\pi\pi^*}$ states may be designated " 1L_b -related" or " 1L_a -related" on the strength of the following computational criteria:

1. The energetic relationship of the computed $^1\Gamma_{\pi\pi^*}$ states of the molecule of interest to the computed 1L_a or 1L_b states of benzene; and

2. The configurational relatedness of the lowest and second lowest-energy $^3\Gamma_{\pi\pi^*}$ states to particular $^1\Gamma_{\pi\pi^*}$ states.

Criterion 1 is illustrated in Figure 32 where the $^1\Gamma_{\pi\pi^*}$ states of the o sub-set are correlated with the $^1\Gamma_{\pi\pi^*}$ states of benzene. The molecules are arranged from left to right in order of increasing $|\mu_o|$. The lowest energy $^1\Gamma_{\pi\pi^*}$ state, the " 1L_b -related" state, shows a moderate decrease in energy accompanied by a slight increase in oscillator strength. The second-lowest energy $^1\Gamma_{\pi\pi^*}$ state, the " L_a -related" state, exhibits a decrease in oscillator strength along with a moderate decrease in energy. These results reproduce the experimental findings rather well. In further support of the L_a/L_b labeling,

Figure S1.
 correlation of $^1L_{\pi,\pi^*}$ (CSD0/s-C.I.) states of o-disubstituted
 benzenes with the $^1L_{\pi,\pi^*}$ states of benzene. The molecules
 are arranged from left to right in order of increasing com-
 puted ground state dipole moment, $|\mu_0|$.

our utilization of criterion 2 shows that the lowest-energy $^3\Gamma_{\pi\pi^*}$ state is configurationally akin to the " 1L_a -related" state, while the second lowest-energy $^3\Gamma_{\pi\pi^*}$ state is configurationally akin to the " 1L_b -related" state. This is precisely the same result as found for the p sub-set. Therefore, we use the simple $^1,^3L_a$ and $^1,^3L_b$ terminology henceforth. The energies of the triplet electronic states are presented in Table 17.

The o sub-set exhibits trends which are both similar and dissimilar to those of the p sub-set. It is observed, as $|\mu_0|$ increases, that

---The 1L_a - 1L_b energy gap decreases slightly. This gap is found to be 1.008eV in o -cyanophenol; 0.941eV in o -cyanoaniline; and 0.866eV in o -nitroaniline.

The experimental data suggest the opposite trend, namely that the 1L_a - 1L_b gap increases slightly with increasing $|\mu_0|$.

---The energy of the 1L_a state decreases at more or less the same rate as does that of the 1L_b state. In going from o -cyanophenol to o -cyanoaniline, for example, the 1L_a decrement is 0.218eV, while the 1L_b decrement is 0.151eV.

---The third and fourth $^1\Gamma_{\pi\pi^*}$ states are undoubtedly related to the 1B states of benzene. This conclusion is based on the energetic relationship of these two states to the 1B state of benzene and their relative energy separations: 0.217eV in o -cyanophenol; 0.283eV in o -cyanoaniline; and 0.286eV in o -nitroaniline. The increase is moderate, but the trend is the same as that exhibited by the P sub-set.

---In the case of o -cyanophenol and o -cyanoaniline, the $^1\Gamma_{\pi(CN)\pi^*}$ and $^1\Gamma_{\pi\pi^*(CN)}$ states lie energetically between the 1L_b and 1L_a states,

as also occurs in the p sub-set.

---The two lowest-energy states of o-nitroaniline are ${}^1\Gamma_{\pi\pi^*}$ states. Two additional ${}^1\Gamma_{\ell\pi\pi^*}$ states also lie at low energies.

---The highest-energy states below 7.0eV are of ${}^1\Gamma_{\sigma\pi\pi^*}$ type in every case.

---The 1L_a - 3L_a energy gap decreases regularly.

---The ${}^1L_a \leftarrow {}^1A$ and ${}^1L_b \leftarrow {}^1A$ transitions are of comparable intensity and $f({}^1L_a \leftarrow {}^1A)/f({}^1L_b \leftarrow {}^1A)$ decreases slowly but regularly. The $f({}^1L_b \leftarrow {}^1A)$ intensities are less for p than for o whereas the opposite is true for $f({}^1L_a \leftarrow {}^1A)$. A selected data set supportive of these assertions is shown in Table 18.

---Intramolecular CT increases but is best described as substituent \leftrightarrow ring. It is comparable in both 1L_a and 1L_b states.

C.

The computed energies, oscillator strengths and transition dipole moment vectors of the singlet electronic states of the m sub-set are presented in Table 19. Following the analysis of the o sub-set, a correlation of the ${}^1\Gamma_{\pi\pi\pi^*}$ states of the m sub-set with the ${}^1\Gamma_{\pi\pi\pi^*}$ states of benzene is presented in Figure 33. The following observations may be made:

---It is found that the lowest-energy ${}^3\Gamma_{\pi\pi\pi^*}$ state is configurationally related to the 1L_a state and that the second lowest-energy ${}^3\Gamma_{\pi\pi\pi^*}$ state is related to the 1L_b state. The energies of the triplet electronic states are collected in Table 20.

---As $|\mu_0|$ increases, one finds an over-all increase in the oscillator strength of the ${}^1L_b \leftarrow {}^1A$ transition and an over-all decrease in the oscillator strength of the ${}^1L_a \leftarrow {}^1A$ transition. o-Cyanoaniline

Figure 33.

Correlation of ${}^1\Pi_{\pi\pi^*}$ (CNDO/s-C.I.) states of m-disubstituted benzenes with the ${}^1\Pi_{\pi\pi^*}$ states of benzene. The molecules are arranged from left to right in order of increasing computed ground state dipole moment, $|\mu_0|$.

is somewhat aberrant in both instances.

---Both the 1L_a and 1L_b states exhibit a moderate decrease in energy as the ground state dipolarity increases. The over-all energetic trends of the 1L_a and 1L_b states are similar to those found for the \underline{p} and \underline{o} sub-set. The 1L_a - 1L_b energy gap appears to decrease slightly as $|\mu_0|$ increases. This gap is 1.013eV in \underline{m} -cyanophenol; 1.000eV in \underline{m} -cyanoaniline; and 0.967 in \underline{m} -nitroaniline. Experiment indicates that this gap is either constant or slightly increasing.

---The 1L_a state decreases in energy more rapidly than does the 1L_b state. Comparing \underline{m} -cyanophenol to \underline{m} -cyanoaniline, the 1L_a decrement is 0.187eV, while the 1L_b decrement is 0.174eV. In going from \underline{m} -cyanoaniline to \underline{m} -nitroaniline, 1L_a decreases in energy by 0.017eV while 1L_b increases in energy by 0.016eV.

---The third and fourth ${}^1\Gamma_{\pi\pi^*}$ states are thought to relate to the 1B states of benzene. This conclusion is based solely on the energetic correlation of these states to the 1B state of benzene.

---Two ${}^1\Gamma_{\pi(CN)\pi^*}$ and ${}^1\Gamma_{\pi\pi^*(CN)}$ states lie energetically between the 1L_a and 1L_b states of \underline{m} -cyanophenol. The ${}^1\Gamma_{\pi\pi^*(CN)}$ state lies above the 1L_a state of \underline{m} -cyanoaniline. A second ${}^1\Gamma_{\pi(CN)\pi^*}$ state is the highest-energy state listed below 7.0eV for \underline{m} -cyanophenol.

---The two lowest-energy states of \underline{m} -nitroaniline are of ${}^1\Gamma_{n\pi^*}$ type. Three ${}^1\Gamma_{\ell\pi^*}$ states also occur at rather low energies. The highest-energy states found below 7.0eV in the case of \underline{m} -cyanoaniline and \underline{m} -nitroaniline are ${}^1\Gamma_{\sigma\pi}$ states.

---The 1L_a - 3L_a gap decreases as $|\mu_0|$ increases.

CHAPTER TWO.
SPECTROSCOPIC STUDIES OF SOME SIMPLE
INORGANIC ANIONS.

Abstract

Two mechanisms which rationalize the non-additivity of certain absorption bands in the spectra of cation - anion complexes are described: charge-transfer transitions and enhanced singlet-triplet transitions. The latter effect is more likely to dominate if the cation is a heavy-metal ion.

The electronic spectra of the chlorite and sulfate ion have been investigated. In the spectrum of the chlorite ion, a transition is observed which is interpreted as a singlet-triplet transition. An examination of the electronic spectrum of the sulfate ion reveals a previously unreported transition which is identified as a singlet-triplet transition.

The tungstate and molybdate ions are known to emit in the solid phase. In the solution spectra of salts of these anions, a previously unreported transition is observed which resembles the emission excitation band. This transition is examined and interpreted as a singlet-triplet transition of the anion.

I. INTRODUCTION

The colors of ionic compounds or complexes can usually be attributed to the combined absorption of the component ions. This effect has been termed the 'Principle of additivity of ionic colors.'¹ It should be noted that the absorptions are subtracted from, not added to, the incident white light.²

Deviations from this rule are common and a partial list of these is given in Table 1 and 2. Efforts to understand the origins of the unusual colors have resulted in the elucidation of different mechanisms of color production.

II. THE CHARGE-TRANSFER MECHANISM

In 1941, Pitzer and Hildebrand published a study of the colors of various iodides.³ The heats of formation, solubilities, and bond distances of these compounds suggested that they were partially covalent. Since essentially ionic compounds can undergo an anion cation electronic charge-transfer transition, the color of the iodides were thought to be due to such a transition. The transition was red-shifted by an amount thought to be proportional to the deviation from pure ionic bonding. This has become known as the 'Pitzer-Hildebrand Rule.'

Jorgensen has developed a method of describing charge-transfer transitions in MX_n^{-m} complexes, where X is a ligand and M is a transition metal.⁴ The regularities exhibited by the ligand metal charge-transfer transition energies of such complexes can be

processed to yield values of 'optical electronegativities' for both the ligand and the metal. Charge-transfer transition energies for different complexes of the same stoichiometry can be calculated, if the optical electronegativities of the metal and ligand were known. By such a procedure, Jorgensen has assigned the transitions causing the intense colors of AgMnO_4 and Ag_2CrO_4 to silver $4d \rightarrow$ anion transitions.⁵ A more complete description of the method, and a table of optical electronegativities may be found in reference 4.

Inter-molecular charge-transfer transitions in inorganic systems have been studied in solution by several workers.⁶⁻¹⁰ Generally, these transitions are fairly intense.⁶ The energies of metal ion \leftrightarrow anion charge-transfer transitions are related to the nature of the metal: if the transition is metal \rightarrow anion, the energy of the transition should be proportional to the $\text{M}^n/\text{M}^{n+1}$ redox potential; if the transition is anion \rightarrow metal, the energy should be proportional to the $\text{M}^n/\text{M}^{n-1}$ redox potential.⁷

In summary, charge-transfer transitions are known to cause non-additive color in many instances, in both solution and the solid phase. The ease of optical oxidation and reduction of the components of the complex determines the energy of the transition. If the transition is of optical frequency, the color will be intense.

III. ENHANCEMENT OF THE SINGLET-TRIPLET TRANSITION

Investigations of a number of colored metal-anion complexes in this laboratory have demonstrated that the transition responsible for the color is the anion $T_1 \leftarrow S_0$ transition, enhanced by the presence of the metal ion via spin-orbit coupling.¹¹ In the colorless nitrite ion, for example, the lowest triplet state has an origin at 18959 cm^{-1} (527.45 nm).¹² A heavy metal ion such as silver is capable of increasing the probability of the $T_1 \leftarrow S_0$ transition to an extent which causes the low color of silver nitrite crystals.¹³

A singlet-triplet transition differs considerably from a charge-transfer transition. The oscillator strength of the former is usually much less than that of the latter. The significant metal attribute in the former is atomic number; in the latter, it is the ease of photo-oxidation or reduction. The singlet-triplet transition must lie at lower energy than the associated singlet-singlet transition whereas the charge-transfer transition has no such restriction. For emissive molecules, the inverse of the singlet-triplet absorption, which is known as phosphorescence, lies at lower energies and has a longer lifetime than the inverse of the charge-transfer absorption (which is known as fluorescence). Other important experimental methods of differentiation exist. The various methods have been outlined in Table 3.

Among the metal ions which induce color in metal-anion complexes are those of the post-transition metals (i.e. Ag^+ , Tl^+ , Hg^{++} , etc.). Having filled d shells, these ions do not undergo d-d

TABLE 3
EXPERIMENTAL METHODS OF DIFFERENTIATING
CHARGE-TRANSFER AND SINGLET-TRIPLET TRANSITIONS

<u>Characteristic</u>	<u>Triplet Mechanism</u>	<u>Charge-Transfer Mechanism</u>
Wavelength	Not affected by use of different metal cations.	Related to the redox potentials of different metal cations.
Intensity	Roughly related to Z^4 , where Z is the atomic number of the metal cation.	No obvious relationship to atomic number of the metal cation.
Position	Lies to the red of the $S_1 \rightarrow S_0$ transition.	Does not necessarily lie to the red of the $S_1 \rightarrow S_0$ transition.
Polarization	Determined by the polarization of the $S_n \rightarrow S_0$ transition from which the $T_1 \rightarrow T_0$ transition gains intensity.	Polarized along the direction of charge transfer.
Emission	Long (10^{-4} sec.) lifetime. Mirror image relationship with the $T_1 \rightarrow S_0$ transition.	Short (10^{-8} sec.) lifetime. Mirror-image relationship with the charge-transfer transition.
Electron Spin Resonance	Has an E. S. R. spectrum.	No E. S. R. spectrum is expected.

transitions which might obscure the anion $T_1 \leftarrow S_0$ transition. Post-transition metals are capable of covalent bonding through donation of electron density from a filled d orbital to the anion, or through the acceptance of electron density from the anion into an empty s or p orbital.¹⁴ In addition, these metal ions are capable of charge-transfer transitions, either $d \leftrightarrow \text{anion}$ or $\text{anion} \leftrightarrow s$ (or p).

There are a number of post transition metal-anion complexes where no non-additive color is observed. However, an additional transition, either quite weak or lying outside the visible region of the spectrum, may be detected. It is likely that this new transition is either a charge-transfer transition or an enhanced singlet-triplet transition. The remainder of this chapter will be devoted to the discussion of several metal-anion complexes where this new transition has been observed.

IV. EXPERIMENTAL METHODS

A. Preparation of Chlorites

Sodium chlorite, analytic grade (Matheson, Coleman, and Bell) was recrystallized from water solution to which a trace of sodium hydroxide had been added in order to stabilize the chlorite ion. Silver chlorite was precipitated from sodium chlorite in water solution by the addition of reagent grade silver nitrate (Mallinckrodt). Silver perchlorate monohydrate (Matheson, Coleman, and Bell) was used as received. Reagent grade silver sulfate was used as obtained.

B. PREPARATION OF SULFATES

Lithium potassium sulfate was prepared from stoichiometric quantities of reagent grade lithium sulfate (Mallinkrodt) and reagent grade potassium sulfate (Faker).

C. MOLYBDATE AND TUNGSTATE CRYSTALS

Silver molybdate was precipitated from a solution of reagent grade sodium molybdate (Merck) by the addition of silver nitrate. The silver molybdate crystal was grown from a solution made by dissolving the filtered precipitate in ammonium hydroxide solution. The thallium tungstate crystal was grown from a water solution containing reagent grade sodium tungstate (Matheson, Coleman, and Bell) and purified thallium nitrate (Fisher Scientific Company).

D. TUNGSTATE SALTS

Cadmium tungstate solution was prepared from a washed precipitate formed by the addition of reagent grade cadmium chloride (Baker) to sodium tungstate in water. Sodium tungstate solution was prepared from reagent grade sodium tungstate, recrystallized from water. Cesium tungstate solution was prepared from 99.9% cesium tungstate from Roc Ric Research. Lead tungstate solution was prepared from a washed precipitate formed by the addition of lead chloride (Apache, 99.999%) solution in water to sodium tungstate solution. Thallium tungstate solution was prepared by dissolving the thallium tungstate crystals described previously.

E. MOLYBDATE SOLUTIONS

Lead molybdate solution was prepared from a washed precipitate formed by the addition of lead chloride solution to a sodium molybdate solution in water. Cadmium molybdate solution was prepared from a precipitate formed by the addition of cadmium chloride solution to a sodium molybdate solution in water. Sodium molybdate solution was prepared from recrystallized sodium molybdate. Ethanol was refluxed over calcium oxide and distilled from magnesium turnings.

F. TUNGSTATE SALTS

The silver tungstate was prepared by the method described above for silver molybdate crystals. The cesium tungstate was used as obtained from Roc Ric Research. Sodium tungstate was recrystallized from water solution and annealed for one hour at 500°C.

G. MOLYBDATE SALTS

Silver molybdate was prepared as described previously. Lead molybdate was prepared by annealing a finely powdered mixture of lead acetate and molybdenum trioxide for 3-4 hours at 900°C. The molybdenum trioxide was prepared by standard methods.¹⁵ Barium molybdate was prepared by annealing a finely powdered mixture of molybdenum trioxide and Baker reagent grade barium carbonate for 3-4 hours at 900°C. Calcium molybdate was prepared by annealing a finely powdered mixture of calcium carbonate and molybdenum trioxide for 2-3 hours at 800°C. Strontium molybdate was precipitated from sodium molybdate solution by the addition

of reagent grade strontium nitrate (Mallinckrodt), and washed with water. Cadmium molybdate was prepared by annealing a finely powdered mixture of molybdenum trioxide and cadmium carbonate for 2-3 hours at 800°C. Bismuth molybdate was precipitated from a solution of sodium molybdate by the addition of bismuth nitrate, then annealed for 6 hours at 400°C and again at 600°C for 5 hours. Zinc molybdate was prepared by annealing a finely powdered mixture of Fisher Scientific Company reagent grade zinc acetate and molybdenum trioxide at 600°C for 5 hours. Sodium molybdate was recrystallized from water.

All absorption spectra were obtained on a Cary model 14 or 15 spectrophotometer in conjunction with a liquid nitrogen contact dewar. Emission spectra were recorded on a Jarrel-Ash Mark V 1/2-meter scanning monochromator with a Princeton Applied Research phase-sensitive detection system and a 500W xenon arc excitation source. All emission spectra were recorded with the sample cooled to 77°K with a liquid nitrogen immersion dewar, and are uncorrected for instrument response. Lifetime measurements were made with a Xenon Corporation Model 437 or EGG Model 550/551 flashlamp with a Tektronix 556 dual beam oscilloscope.

V. THE CHLORITE ION

The chlorite ion, ClO_2^- , is a unique twenty-electron anion. The ultraviolet spectrum of sodium chlorite is characterized by two weak transitions, a maximum at 264 nm and a shoulder at 310 nm, in ethanol (Figure 1). The corresponding values in water solution are 260 nm and 290 nm. These transitions have been assigned by Friedman¹⁰ (after Mulliken¹¹) as $B_2 \leftarrow A_1$ and $B_1 \leftarrow A_1$, respectively. Calculations on the chlorite ion performed by the author¹⁸ lead to assignments of $B_1 \leftarrow A_1$ and $A_2 \leftarrow A_1$, respectively, for these two transitions.

A third, very weak transition, 360 nm in Figure 1, is of particular interest. The transition is more apparent in the spectrum of silver chlorite doped into a silver perchlorate lattice (Figure 2). The entire spectrum is red-shifted in Figure 2 as compared to Figure 1, but the relative positions of the three bands are unchanged.

The intensity of the 360 nm transition, assuming it is intrinsic to the chlorite ion, is $\sim 7 \text{ l/mole cm}$ in Figure 2. Charge-transfer transitions are much more intense.⁸ Also, a charge-transfer transition is likely to undergo a more significant shift in energy when the metal cation is changed from Na^+ to Ag^+ than is seen in Figures 1 and 2. The singlet-triplet interval in Figure 1, assuming the 360 nm transition is the triplet and the 310 nm transition is the associated singlet, is $\sim 0.5 \text{ eV}$, similar to that of sodium nitrite.¹²

The intensity of the 360 nm transition, and its position

relative to the two stronger transitions, lead to the assignment of the 360 nm transition as the $T_1 \leftarrow S_0$ transition.

VI. THE SULFATE ION:

Previously published absorption spectra of the sulfate ion, $\text{SO}_4^{=}$, indicate the onset of an absorption band at 200 nm.^{6,19} Our investigations have revealed an additional transition observed at 270 nm in room temperature solutions of silver sulfate (Figure 3). The transition is also observed in thallium sulfate solutions at the same wavelength, though at much lower intensity. The transition is difficult to observe, as it is easily obscured by the nearby, more intense (~ 600 l/mole·cm) Ag^+ transition at 225 nm. Concentration changes or the addition of Ag^+ or $\text{SO}_4^{=}$ ions cause changes of intensity and energy in the transition (Figure 4). One may conclude that the degree of cation-anion association has a large effect on the transition characteristics.

The transition may also be observed in Ag^+ doped LiKSO_4 crystals (Figure 5). Upon cooling from room temperature to 77°K, the band intensity increases but without an increase in resolution.

The intensity of the band may be roughly calculated by assuming that the transition is due to the isolated sulfate ion. Based on the intensity of the Ag^+ transition at 210 nm ($\epsilon \sim 1000$ l/mole·cm),⁶ the 270 nm band has an extinction coefficient of ~ 600 l/mole·cm. This is an acceptable value for the extinction coefficient of a charge-transfer transition, but is somewhat high for a $T_1 \leftarrow S_0$ transition. The $T_1 \leftarrow S_0$ transition in metal nitrite solutions are less intense.²⁰ However, the related $S_1 \leftarrow S_0$ transition in the nitrite ion is considerably less intense ($\epsilon \approx 30$ l/mole·cm)²¹ than that of the sulfate ion.⁶

The 270 nm transition is not observed in solutions of sodium

Figure 3.

sulfate in water.¹⁹ This fact indicates that the solution is not a sulfate ion charge-transfer-to-solvent transition. The fact that the transition appears at the same wavelength in the thallium and silver salt solution spectra, but does not appear in the spectrum of the sodium salt solution is consistent with the characteristics of a singlet-triplet transition.

The 270 nm transition is energetically distant from the sulfate $S_1 \rightarrow S_0$ transition. Assuming that the 270 nm transition is the $T_1 \leftarrow S_0$ transition and the associated singlet transition is at 180 nm,⁶ the singlet-triplet interval would be 2.3 eV. Although this is a large interval, it is not unprecedented. The tetrahedral ions discussed in the next section have singlet-triplet intervals of 1.6 eV.

Sulfate ions have no intrinsic luminescence in solution, so that a triplet state cannot be located by this means.

With the above experimental considerations in view, we propose to assign the 270 nm transition shown in Figures 3-5 as the sulfate ion $T_1 \leftarrow S_0$ transition.

VII. TUNGSTATES AND MOLYBDATES:

The tungstate, molybdate, and vanadate ions are d^0 , tetrahedral ions which luminesce in the solid phase.²²⁻²⁸ They also act as efficient sensitizers for rare-earth emission^{22,29-30} The observed emission is not defect, impurity, or band emission, but is a self activated molecular emission from the oxyanion. The related oxyanions permanganate, pertechnetate, and chromate do not emit. None of the anions, for reasons that are not clear, emit in the liquid phase.

The absorption and emission spectra of a number of tungstate and molybdate salts have been investigated. The absorption spectra of the salts in water solution are shown in Figures 6 and 7, and summarized in Table 4. The absorption edges seen at higher energies are the onsets of an intense singlet-singlet transition due to the anion. For the molybdate ion, the band maximum of this transition is ~ 227 nm; for the tungstate ion, the maximum is ~ 200 nm. For a given ion, the position of the absorption edge changes because of the different concentrations required to observe the weaker transition to the red of the edge. It is this weaker transition that is of interest.

The energies of the weak bands do not correlate with metal redox potentials. Na_2WO_4 has the lowest energy weak band, yet Na^+ is one of the most difficult ions to reduce ($\text{Na}^+ + e = \text{Na}$, $E = -2.714$ V³¹). The weak bands, which show some variation in band maxima, would show less if the absorption due to the underlying singlet-singlet transition could be accurately subtracted out. More variation

in band maxima would be expected if the transition were a ligand \rightarrow metal charge-transfer transition. In general, the metal ions used are not those expected to be easily reduced photochemically.

The possibility that the bands are due to metal solvent transitions was investigated by recording the spectra of the metal chlorides in neutral water solutions. Thallium chloride solution has an absorption band at 212 nm, lead chloride absorbs at 208 nm. The other metal ions had no absorptions which resemble those in Figures 6 and 7, in agreement with the literature.³²⁻³⁴

Are the transitions singlet \rightarrow triplet? Examining intensities first, a difficulty arises because the extinction coefficients are quite difficult to measure. The values listed in Table 4 were computed assuming that the isolated anion was the absorbing species. With that assumption, it is evident from Table 4 that the transition probability generally increases with increase of cation atomic weight. This is a characteristic effect of heavy atoms on singlet-triplet transitions.³⁵ It may be added that the transitions are also quite weak.

The singlet-triplet intervals are similar for both anions (1.6 eV), assuming the singlet and triplet energies respectively are 227 and 320 nm ($\text{MoO}_4^{=}$), and 200 and 279 nm ($\text{WO}_4^{=}$). This is an acceptable value: for $\text{Cd}(\text{NCO})_2$ the interval is 1.5 eV,³⁶ for $\text{Zn}(\text{SCN})_2$ the interval is 2.0 eV.³⁷

Additional evidence of the triplet nature of the weak transition is provided by the emission characteristics of molybdate and

tungstate salts. Representative emission spectra obtained at 77°K are shown in Figures 8 and 9. The emission bands are nearly gaussian.³⁷ No correlation with cation reduction potentials exists, indicating that the transition is not charge-transfer.

The wavelengths of maximum excitation and emission, and the lifetimes of the emission of several molybdate and tungstate salts are given in Tables 5 and 6. The few salts for which temperature dependencies of emission have been reported^{25,27,38} show a plateau at or near 77°K, below which the lifetimes increase. The lifetimes listed in Tables 5 and 6 were obtained at 77-82°K.

The following conclusions from the emissive lifetimes can be drawn. First, the lifetimes are quite short for $T_1 \rightarrow S_0$ emission, but not unprecedented.³⁹ They reflect the strong spin-orbit coupling perturbation of the heavy nuclei involved. Second, the lifetime of a molybdate salt is almost always greater than that of the tungstate salt of the same cation. Third, the heavier the cation, the shorter is the lifetime. The clarity of this observation is obscured somewhat by the effects of trapping levels, methods of preparation, impurities, and temperature effects.^{25,27,38} If the conclusions are genuine, they are consistent with the effects of external heavy atoms on a $T_1 \rightarrow S_0$ transition.³⁵

Normally, the excitation spectrum of an emitting molecule closely resembles its absorption spectrum.⁴⁰ The excitation maxima listed in Tables 5 and 6 lie far to the red of the strong singlet-singlet transitions of the molybdate ion (227 nm) and the tungstate

ion (200 nm) in solution. In most cases, the excitation maxima correlate with the weak transitions listed in Table 4.

The single crystal specular reflection spectra of silver molybdate and thallium tungstate have been obtained,⁴¹ and are shown in Figure 10. Specular reflection bands correspond roughly to absorption bands, except that the reflection band maxima are shifted to the red.⁴² Silver molybdate has a reflection band at 300 nm which corresponds closely with its emission excitation maximum at 295 nm. The 250 nm band is probably a transition in Ag^+ (225 nm in solution). The solution absorption spectrum of silver molybdate does not unequivocally show a transition near 300 nm, partially because of Tyndall scattering by silver molybdate particles.

The specular reflection spectrum of thallium molybdate shows a band at 293 nm and several shoulders to the blue of that band which may correspond with the weak solution band at 263 nm.

In summary, both specular reflection spectra show bands other than those related to the anion and cation solution spectra. Further, the bands observed show a correspondence with the weak transitions seen in the solution spectrum (thallium tungstate) and with the emission spectrum (silver molybdate).

The most rational explanation for the above observation is the assignment of the weak transition observed in solution, and the intrinsic molecular emission of molybdate and tungstate ions as due to the $T_1 \leftrightarrow S_0$ transition.

CHAPTER THREE.

SPIN-ORBIT COUPLING IN ~~THE~~ THE SILVER NITRITE MOLECULE.

Abstract

A model which describes the interaction between a metal cation and an inorganic anion is developed using first-order perturbation theory. The model does not invoke vibronic spin-orbit coupling. All one-electron excitations of the highest-occupied and lowest-occupied metal and anion orbitals are investigated. Expressions which describe all sources of $S_0 \leftrightarrow T_1$ intensity are derived and given. These expressions are computed for the silver nitrite molecule and are compared with experiment. The results indicate the critical role of charge-transfer transitions in the mechanism of the enhancement of $T_1 \leftrightarrow S_0$ probabilities.

I INTRODUCTION:

The nitrite ion, a nonlinear eighteen electron molecule, is characterized by three singlet transitions below 200 nm:¹ an intense $\pi\pi^*(B_1 \leftarrow A_1)$ transition at 210 nm and two $\pi\pi^*$ transitions, one at 350 nm ($B_1 \leftarrow A_1$) and the other at 290 nm ($A_2 \leftarrow A_1$), in solution. The lowest triplet state has been identified as a 3B_1 .^{2,3,4} In sodium nitrite, the ${}^3B_1 \leftarrow {}^1A_1$ transition is polarized almost entirely in plane, perpendicular to the two-fold axis (y-polarization). Zeeman studies^{2,4} indicate that the zero-field spin state is T_z (A_2). The phosphorescence spectrum exhibits quite weak non-totally symmetric vibrations, thus disallowing a vibronic spin-orbit coupling mechanism. The transitions ${}^1B_2 \leftarrow {}^1A_1$ and the ${}^1B_1 \leftarrow {}^1A_2$ have been suggested as primarily candidates for the ${}^3B_2 \leftarrow {}^1A_1$ transition intensity.^{2,4,5}

An enhancement of the $T_1 \leftarrow S_0$ absorption is known to occur with heavy metal salts or solutions of nitrite.⁶ For example, silver is observed to increase the oscillator strength of that transition by two orders of magnitude in the crystal,⁷ thallium by three.⁸ In contrast to the case of sodium nitrite, in silver sodium nitrite ($AgNa(NO_2)_2$) the polarization of the $T_1 \leftarrow S_0$ absorption is totally along the two-fold (z) axis.⁷ In silver nitrite, evidence exists that the emitting triplet is the 3A_2 .⁹ In this salt, a charge-transfer transition previously predicted⁵ is observed at 390 nm.⁹

The silver nitrite molecule has thus been well described experimentally. In addition, the enhanced $T_1 \leftarrow S_0$ transition mech-

anism is known to operate in this molecule.^{5,6} For those reasons, a more thorough quantum mechanical description of silver nitrite has been developed. It is hoped that general conclusions which are helpful in the understanding of other metal-anion systems will be generated.

II. THE MODEL:

The model describes the enhancement of the anion $T_1 \leftarrow S_0$ transition via spin-orbit coupling. It is assumed that the electronic structure of the isolated anion and metal cation are known. All interactions are restricted to the highest-occupied and lowest-unoccupied spinorbitals of the anion and the metal. We denote the highest-occupied and lowest-unoccupied spinorbitals of the anion as a and a^* , respectively. Similarly, for the metal, we use m and m^* , respectively. In the case of the nitrite ion, for example, a may represent any one of the a_2 , b_2 , or a_1 spinorbitals, all of which are occupied in the ground state (vide supra).

At large metal-anion distances, the spinorbitals, as written above, remain orthogonal. The possible electronic configurations derived from these four spinorbitals (assuming no interaction between the metal and the anion) are given by the wave functions of Table 1. These wave functions will be denoted the zero-order wave functions. Only single-electron excitations have been included in Table 1. These wave functions are neither orthogonal nor normalized. The five con-

TABLE 1

		$\frac{1}{\sqrt{2}}(a\bar{a}m\bar{a}^* - a\bar{a}a^*m\bar{m})$	0

figurations shown have immediate spectrochemical interpretations, which are illustrated in Figure 1.

The spinorbitals a and a^* are eigenfunctions of the total hamiltonian of the anion,

$$H_a = \sum_{i=1}^{N_a} \left(-\frac{1}{2} \nabla_i^2 + \sum_{j \in a} \frac{1}{r_{ij}} - \sum_x \frac{Z_x}{r_{ix}} + \sum_x \xi \vec{l}_x \cdot \vec{s}_i \right) \quad (1)$$

and m and m^* are eigenfunctions of the total hamiltonian of the metal,

$$H_m = \sum_{p=1}^{N_m} \left(-\frac{1}{2} \nabla_p^2 + \sum_{q \in m} \frac{1}{r_{pq}} - \frac{Z_m}{r_{pm}} + \xi \vec{l}_m \cdot \vec{s}_p \right) \quad (2)$$

where i , j , p , and q are electron indices, N_a is the total number of electrons in the anion, N_m is the total number of electrons in the metal, x is the atomic center index, and ξ is the spin-orbit coupling coefficient.

At wide separation, where there is no overlap between the metal and the anion, the total hamiltonian of the metal + anion complex is just $H_a + H_m$. We will follow a first-order perturbative description. As the ions are brought closer and allowed to interact, there is an additional term H' in the total hamiltonian H_t :

$$H_t = H_a + H_m + H' \quad (3)$$

where

$$H' = \left(\sum_a \sum_p \frac{1}{r_{ap}} \right) - \left(\sum_q \sum_{x \in a} \frac{Z_x}{r_{qx}} + \sum_a \frac{Z_m}{r_{am}} \right) + \left(\sum_{x \in a} \frac{Z_x Z_m}{r_{xm}} \right) + \left(\sum_x \sum_i \xi \vec{l}_x \cdot \vec{s}_i \right) \quad (4)$$

The right side of equation (4) has been grouped into four

FIGURE 1

ILLUSTRATION AND INTERPRETATION OF THE FIVE CONFIGURATIONAL
WAVE FUNCTIONS

terms. The first term describes the repulsion of electrons on the metal by the electrons on the anion (and vice versa); the second describes the attraction of the metal nucleus for the electrons of the anion (and vice versa); the third describes the metal nucleus - anion nuclei repulsions; and the fourth describes the spin-orbit coupling. We make the assumption that only the fourth term will influence the probability of the $T_1 \leftarrow S_0$ transition of the anion. Hereafter, H' will denote the spin-orbit coupling term.

The effect of the perturbation H' on the configurational zero-order wave functions of Table 1 will be to mix singlet wave functions with triplet wave functions. This mixing permits the singlet triplet transition to exhibit a non-zero intensity, as is discussed in the next section.

III. SINGLET-TRIPLET TRANSITION DIPOLE MOMENTS:

The intensity of an electric dipole transition $\Psi_1 \rightarrow \Psi_2$ is proportional to the square of the transition dipole moment \vec{M} , given by

$$\vec{M} = \langle \Psi_2 | \sum_i e \hat{r}_i | \Psi_1 \rangle \quad (5)$$

where \hat{r}_i is the coordinate of the i^{th} electron, e is the electron charge, and the wave functions Ψ_1 and Ψ_2 are the total wave functions for the molecule in the initial and final states, respectively.

Assuming an LCAO (Linear Combination of Atomic Orbitals) description of the electronic states Ψ_1 and Ψ_2 , if Ψ_1 is a singlet

and Ψ_2 is a triplet state, \bar{M} becomes, for a $2n$ -electron molecule,

$$\begin{aligned}\bar{M} &= \langle {}^3\Psi_2 | \sum_i e \hat{r}_i | {}^1\Psi_1 \rangle \\ &= \langle \varphi_{1\alpha} \cdot \varphi_{1\beta} \cdots \varphi_{n\beta} \cdot \varphi_{n+1\beta} | \sum_i e \hat{r}_i | \varphi_{1\alpha} \cdot \varphi_{1\beta} \cdots \varphi_{n\alpha} \cdot \varphi_n \cdot \beta | \rangle \\ &= \langle \varphi_{n+1} | e \hat{r} | \varphi_n \rangle \langle \beta | \alpha \rangle \\ &= 0,\end{aligned}$$

where φ_n is the space, and α (β) is the spin function of the spinorbital. The $M_S = -1$ spin component of the triplet state ${}^3\Psi_2$ was used above, but similar expressions for the other two spin components also have a zero transition dipole moment.

The above equations demonstrate that a pure singlet \leftrightarrow triplet transition has a zero transition dipole moment. How, then, is this transition ever observed? The answer lies in the mixing of singlet and triplet wave functions by spin-orbit coupling.¹⁰

Using the wavefunctions of Table 1, the (singlet) ground state is ${}^1\Psi_0$ and the triplet state is ${}^3\Psi_{A*}$, for the anion singlet \leftrightarrow triplet transition. Spin-orbit coupling will allow the mixing in of an excited singlet state, for example ${}^1\Psi_{CT}$, into ${}^3\Psi_{A*}$. The resulting wave function is designated ${}^3\Psi_{A*}'$, given by

$${}^3\Psi_{A*}' = {}^3\Psi_{A*} + e''' {}^1\Psi_{CT}. \quad (6)$$

The coefficient e''' is expressed, using first-order perturbation theory,

$$\text{by} \quad e''' = \frac{\langle {}^1\Psi_{CT} | H' | {}^3\Psi_{A*} \rangle}{{}^3E_{A*}^0 - {}^1E_{CT}^0} \quad (7)$$

where ${}^3E_{A*}^0$ and ${}^1E_{CT}^0$ are the energies of the metal-anion complex in the electronic states ${}^3\Psi_{A*}$ and ${}^1\Psi_{CT}$ without spin-orbit coupling, re-

spectively. The transition dipole moment \bar{M} for the transition ${}^3\Psi_{A*}'$, Ψ_0 becomes

$$\begin{aligned}
 \bar{M} &= \langle {}^3\Psi_{A*}' | \Sigma e \hat{r} | \Psi_0 \rangle \\
 &= \langle ({}^3\Psi_{A*} + e''' {}^1\Psi_{CT}) | \Sigma e \hat{r} | \Psi_0 \rangle \\
 &= \langle {}^3\Psi_{A*} | \Sigma e \hat{r} | \Psi_0 \rangle + e''' \langle {}^1\Psi_{CT} | \Sigma e \hat{r} | \Psi_0 \rangle \\
 &= 0 + \frac{\langle {}^1\Psi_{CT} | H' | {}^3\Psi_{A*} \rangle}{{}^3E_{A*}^0 - {}^1E_{CT}^0} \langle {}^1\Psi_{CT} | \Sigma e \hat{r} | \Psi_0 \rangle \quad (8) \\
 &\neq 0.
 \end{aligned}$$

Each of the five excited singlet states may be able to mix with the anion triplet state ${}^3\Psi_{A*}$. Thus the full expression for ${}^3\Psi_{A*}'$ would be

$${}^3\Psi_{A*}' = {}^3\Psi_{A*} + b''' {}^1\Psi_0 + c''' {}^1\Psi_{A*} + d''' {}^1\Psi_{M*} + e''' {}^1\Psi_{CT} + f''' {}^1\Psi_{RCT},$$

where the coefficients are expressed in a manner similar to equation 7. However, if we insert the full expression into equation 8, the result is too unwieldy and not instructive. Instead we will consider separately each of the following spin-orbit coupling corrected configurational wave functions:

$$\begin{aligned}
 {}^3\Psi_{A*}' &= {}^3\Psi_{A*} + b''' {}^1\Psi_0 \\
 " &= " + c''' {}^1\Psi_{A*} \\
 " &= " + d''' {}^1\Psi_{M*} \\
 " &= " + e''' {}^1\Psi_{CT} \\
 " &= " + f''' {}^1\Psi_{RCT}.
 \end{aligned}$$

Spin-orbit coupling may also mix triplet states into the ground state, this process also leads to non-zero transition dipole

moments for the singlet \rightarrow triplet transition. The spin-orbit coupling corrected grand state configurational wave functions are, by analogy to the above

$$\begin{aligned}\psi_0' &= \psi_0 + b'' \, {}^3\psi_{A*} \\ '' &= '' + c'' \, {}^3\psi_{M*} \\ '' &= '' + d'' \, {}^3\psi_{CT} \\ '' &= '' + e'' \, {}^3\psi_{RCT}\end{aligned}$$

The expressions for \tilde{M} using each of the nine spin-orbit coupling corrected configurational wave functions listed above are easily worked out. In addition, it is possible to expand the configurational wave functions, using Table 1, into linear combinations of one-electron orbitals. The result will be a large number of expressions for \tilde{M} , using one-electron orbitals instead of configurations. Since the H' and $\sum_i \epsilon_i$ operators are one-electron operators, many of these expressions will be zero. The expressions which are non-zero are given in Table 2. The Table lists only the expressions for the H_z component of H' ,¹¹ the analogous expressions for H_x and H_y are similar except for numerical coefficients. The spin operator matrix elements were evaluated using Table 3.

The following conclusions may be drawn from Table 2.

- 1) No intensity is conferred upon the singlet \leftrightarrow triplet transition from the mixing of excited metal triplet states into the ground state. This is because the triplet - triplet transition ${}^3\psi_{M*} \rightarrow {}^3\psi_{A*}$ is a two-electron transition and is therefore forbidden.

$\langle \bar{a} H b \rangle$	$\langle a H_y' b \rangle$	$i \langle a H_x' b \rangle$	0
$\langle \bar{a} H \bar{b} \rangle$	0	0	$-\langle a H_z' b \rangle$

* where $H' = \frac{1}{2} \hbar \sum_n \mathbf{S}_n \cdot \mathbf{I}_n$. Taken from reference 11, p. 343.

Superscript - above a letter designates a β spin; otherwise, the spin is α .

2) No intensity is derived from the mixing of excited metal singlet states into ${}^3\Psi_{A*}$. d''' is zero because ${}^3\Psi_{A*}$ and ${}^1\Psi_{M*}$ differ by two orbitals, while the operator H_2' is a one-electron operator.

3) It is common to make the assumption that all two-center spin-orbit coupling integrals (e.g., $\langle a* | H_2' | m \rangle$) are zero.¹¹ With this assumption, expressions c, d, h, and i are zero.

4) Expression f does not include any contribution from the metal. It therefore cannot describe the enhancement of the singlet - triplet transition due to the presence of the metal.

5) The remaining expressions, a and e, describe transition intensity arising from the dipolar nature of the ion. Such a mechanism for the enhancement of intensity has been observed previously and described.^{12,13} However, if this is the only mechanism operating, one would expect the enhancement of the singlet - triplet transition intensity to be independent of the nature of the metal ion, which is contrary to what is observed.

The inability of the expressions in Table 2 to relate to experiment is due to the exclusion of metal-anion overlap. This assumption was made in the expansion of the configurational wave functions by taking the one-electron orbitals a , a^* , m , and m^* (Table 1) to be orthogonal. A method for the evaluation of matrix elements of a non-orthogonal basis set has been given by Lowdin.¹⁴ According to him,¹⁴ the matrix element of a one-electron operator Ω_1 with respect to two Slater determinants U and V is given by:

$$\int U^* \Omega_1 V dx = \sum_{k\ell} \{k | \Omega_1 | \ell\} D_{UV}(k | \ell)$$

where k is an element of U , ℓ is an element of V , and $D_{UV}(k | \ell)$ is the minor of the overlap matrix $\int U^* V dx$, produced by striking out the k^{th} row and the ℓ^{th} column of the matrix.

The inclusion of overlap by the above method is possible for both the spin-orbit coupling integral and the transition moment integral. The resulting expressions for \bar{M} using each of the nine spin-orbit coupling corrected configurational wave functions previously listed are given in Table 4.

A considerable reduction in the complexity of these expressions can be achieved by the use of the following:

1. Two-center spin-orbit coupling integrals (e.g., $\langle a | H' | m \rangle$) will be small because of the strong inverse dependence of the spin-orbit coupling constant ξ on distance, and may be neglected.¹¹

2. The spin-orbit coupling operator is not able to mix wave functions which differ in the quantum number ℓ .¹⁵ If the metal under consideration is a post-transition metal, the metal filled orbital m will be a d orbital and the unoccupied orbital m^* will be either an s or p orbital. Therefore, spin-orbit coupling integrals of the type $\langle m | H' | m^* \rangle$ will be zero.

3. The expansion of many of the expressions listed will produce terms with overlap in the second power. These terms will be small and may be neglected. This has been done in Table 4.

Because the orbital designations a , a^* , m , and m^* may each

* μ_O is the dipole moment of the ground state; μ_{A^*} is the dipole moment of the ${}^3\Psi_{A^*}$ state. H' refers to H_z' . Sam is the overlap between the anion orbital a and the metal orbital m .

represent more than one orbital in a particular molecule (in the original definition), it is important to determine whether this ambiguity exists in the expressions in Table 4. For this determination, most of the expressions were recalculated using six-orbital wave functions: the four listed on Table 1 plus two 'dummy' orbitals. For example, the following wave functions would be appropriate to determine if the two a orbitals in the integral $\langle a | H' | a \rangle$ (expression f, Table 4) must be identical:

$$^1\Psi_{A*} = \frac{1}{\sqrt{2}} (|a\bar{a}*b\bar{b}m\bar{m}| + |a*\bar{a}b\bar{b}m\bar{m}|)$$

$$^3\Psi_{A*} = \frac{1}{\sqrt{2}} (|a\bar{a}*b\bar{b}m\bar{m}| - |a*\bar{a}b\bar{b}m\bar{m}|)$$

It turns out that they must be identical, and since H' cannot be totally symmetric in a number of symmetries (including C_{2v}), the integral is zero in molecules with those symmetries.

The expressions for \vec{M} including the approximations described on the previous page and the identity discussed above are given in Table 5. The molecular symmetry is assumed to be C_{2v} . No other refinements are required prior to the application of the model to a particular molecule.

*The primed orbitals have the following meaning: Within a particular expression, all primed orbitals of a single type (e.g., a') must represent the same LCAO wave function. Unprimed orbitals may represent any LCAO wave function of that class (i.e., a may be any of the filled anion orbitals). Other symbols are explained in the footnote to Table 4.

IV. NUMERICAL RESULTS:

It is possible to evaluate numerically all of the expressions in Table 5 for the silver nitrite molecule. This will require reasonably accurate values for the following:

1. Spin-orbit coupling integrals (e.g., $\langle a^* | H' | a \rangle$).
2. The dipole moment of silver nitrite in the ground and $^3\Psi_{A^*}$ state.
3. Overlap integrals between nitrite molecular orbitals and silver atomic orbitals.
4. Transition dipole moments for nitrite molecular orbitals and silver atomic orbitals.
5. The energies of the silver nitrite molecule in the various electronic configurations listed on Table 1.

In order to determine these quantities, a number of computer programs were utilized on the L. S. U. IBM 360/65 computer:

1. CNDO/S-C.I. (Quantum Chemistry Program Exchange CNDO 174): This program was used to calculate nitrite anion wavefunctions and eigenvalues. CNDO/S-C.I. is of the type originated by Pople.¹⁶ It uses the Mataga-Nishimoto approximation¹⁷ for two-center integrals and a configuration-interaction subroutine in which the first thirty mono-excited configurations are used.
2. Zipmol: A non-iterative extended Huckel program written by R. Hoffman, which uses single-zeta Slater-type orbitals. It was used for overlap integral evaluations only. Zeta values which were opti-

mized for proper overlaps (i.e., overlap matched atomic orbitals), were taken from L. E. Harris, H. J. Maria, and S. P. McGlynn⁵.

3. Zevc: An iterative, double zeta, Slater-type orbital, extended Huckel program was used for dipole moment calculations and for whole molecule (AgNO_2) calculations. The coulomb integrals were approximated by negative valence state ionization potentials (-VSIP).⁵ The resonance integrals were obtained by Cusach's approximation:¹⁸

$$H_{ij} = \frac{1}{2} (2 - |S_{ij}|)(H_{ii} + H_{jj}).$$

4. Soced: This program, written by L. Vanquickenborne, calculates singlet-triplet transition moments and lifetimes from Löwdin orthogonalized molecular orbitals obtained from Zevc. Only one-center spin-orbit coupling integrals are evaluated.¹⁹

5. CNDO/2 (a modified version of Quantum Chemical Program Exchange Nr. 141), and Gaussian-70 were used for comparison to cndo/s-C.I. nitrite eigenvalues.

It is important to begin with accurate eigenvectors and eigenvalues for the nitrite ion. The MO order of and the MO energies of the nitrite ion are quite dependent on the type of calculation used (Figure 2). Figure 2 also shows the approximate band half-widths from the only available ESCA spectrum of the NO_2^- ion.²⁰

In all the calculations except Gaussian-70 and Zevc the three highest-occupied orbitals are of the same symmetry and are separate from the fourth highest-occupied orbital. The latter point is in apparent agreement with the photoelectron spectrum.

Figure 2.

Orbital energies of the nitrite ion. All calculations are from reference 21, using atomic dimensions from crystal structure data,²² except the ab initio calculation. The latter was taken from reference 23. The orbital exponents used in Zevc were from E. Clementi.²⁴ The lowest unoccupied orbital is denoted by a box. The lowest unoccupied orbital as calculated by the CNDO/2 program was too high in energy to be included in the diagram.

The lowest-unoccupied orbital is energetically separated from the second lowest unoccupied orbital in all calculations used. The symmetry of this orbital is the same (b_1) in all calculations except Gaussian-70. Transitions from the aforementioned three highest occupied orbitals to the b_1 unoccupied orbital are observed in the ultraviolet spectrum of the NO_2^- ion.¹ (The reason for the non-agreement of the Gaussian-70 data is not known.)

It is evident from the above that the lowest-energy electronic transitions involve primarily the highest three occupied orbitals and the lowest unoccupied orbital. These four orbitals are shown in Figure 3, taken from the CNDO/S-C.I. calculation. The anion a orbital (Table 1) is taken to be any of the three highest occupied orbitals, and the a^* orbital is taken to be the b_1 unoccupied orbital.

The orbital energies from the CNDO/S-C.I. calculation agree best with the photoelectron spectrum energies (Figure 2). For this reason, eigenvectors (orbital exponents and atomic orbital coefficients) from this calculation were used for the analytic form of the anion a and a^* orbitals (Table 6). All atomic orbital contributions of $> 10\%$ were included. The coefficients were rounded off to three significant figures.

The molecular geometry of the nitrite ion varies, according to x-ray crystallographic studies of nitrite crystals,²² with the metal cation. The geometry chosen for all the calculations reported here is from the crystal structure of silver nitrite.²²

Figure 3.

The orbitals of the nitrite ion. The b_1 orbital is the lowest unoccupied orbital. The molecular z axis is the C_{2v} axis, the y axis is in-plane. The b_1 and a_2 orbitals have a node in the yz plane. The orbitals were drawn using data from a CNDO/s-C.I. calculation.²¹

ORBITAL EXPONENTS¹

Nitrogen	2s	$\zeta = 1.95$
	2p	$\zeta = 1.95$
Oxygen	2s	$\zeta = 2.275$
	2p	$\zeta = 2.275$

¹ From CNDO/2-C.I. Analytic form of the orbital is $\psi = Ar^{n-1}e^{-\zeta r}Y_{lm}(\theta, \varphi)$ where A is the normalization factor, n is the principle quantum number, and $Y_{lm}(\theta, \varphi)$ is the spherical harmonic.

²Nitrite geometry from R. E. Long and R. E. Marsh, Acta Cryst., **15**, 448 (1962).

In silver nitrite,²² a silver atom is located along the C_{2v} axis of the nitrite ion 2.47 \AA away from the nitrogen atom in both directions. It is impossible to predict a priori which geometry is important for the interaction which enhances the anion $T_1 \leftarrow S_0$ transition. For this reason, parallel calculations in the two geometries were carried out. The geometry in which the silver atom is located away from the oxygen atoms is denoted 'Structure I,' the geometry in which the silver atom is located nearer the oxygen atoms is denoted 'Structure II.' (Figure 4).

In a previous analysis of the silver nitrite molecule,⁵ the silver - nitrogen distance was taken to be 2.5 \AA . In addition, only one molecular geometry was used (Structure I). In the calculations presented here, the more accurate silver - nitrogen distance (2.47 \AA) and both molecular geometries were used.

The zeta values for the silver $4d$, $5s$, and $5p$ wave functions were taken from reference 5. These were used for the calculation of the overlap matrix for the silver nitrite molecule, using Zipmol. The resulting overlap matrix was used for the calculation of transition dipole moments (vide infra), and for use with Zevc.

A. METAL-ANION OVERLAPS:

The evaluation of the expressions in Table 5 require the calculation of a number of metal - anion overlaps, e.g., S_{am} , S_{a^*m} , etc. The calculation is straightforward: the appropriate atomic orbital

Figure 4.

The two structures of the silver nitrite molecule used in the present calculations. The upper structure is denoted Structure I, the lower is denoted Structure II. Only the position of the silver atom changes in the two structures, the nitrite atomic coordinates remain unchanged. The data was taken from an X-ray crystallographic study of the silver nitrite crystal (reference 22).

overlaps are taken from a Zipmol output. The results are given in Table 7.

B. SPIN-ORBIT COUPLING INTEGRALS:

The spin-orbit coupling integrals $\langle a | H' | a^* \rangle$, etc., are calculated as follows: In order for the integral to be non-zero, it is required that

$$\Gamma_a \times \Gamma_{H'} \times \Gamma_{a^*} \supset \Gamma_{A_1}.$$

If a is ψ_{a_1} and a^* is ψ_{b_1} , then H' must transform as $B_1(P_y)$, a rotation about the y axis. Expansion into atomic orbitals yields

$$\langle \psi_{a_1} | H'_y | \psi_{b_1} \rangle = \langle \sum_i C_i^{a_1} \varphi_i | \frac{1}{2} \sum_k \xi_k \hat{L}_k^y \cdot \hat{s}_k | \sum_j C_j^{b_1} \varphi_j \rangle \quad (9)$$

where φ_i and φ_j are the anion atomic orbitals which comprise the ψ_{a_1} and ψ_{b_1} molecular orbital functions (Table 6) respectively; where k denotes an atomic center (nitrogen, oxygen-1, or oxygen-2); where $C_i^{a_1}$ and $C_j^{b_1}$ are the atomic orbital coefficients for the ${}^1\psi_{a_1}$ and ${}^1\psi_{b_1}$ molecular orbital functions; where ξ_k is the spin-orbit coupling coefficient for atomic center k ; and where \hat{L}_k^y and \hat{s}_k are the orbital and spin operators for atomic center k , respectively.

Since the coordinates of the spin function are not the same as position coordinates of the electrons, the integration over the spin coordinates can be performed independently. Only certain eigenvalues of the spin operator are non-zero, these have been tabulated in Table 3. The spin operator acts upon the configurational wave functions (Table 1) and has been evaluated in Table 5.

It is advantageous to replace the theoretical spin-orbit coup-

TABLE 7

OVERLAPS FOR SILVER NITRITE

ling coefficient ξ_k with the empirical parameter ζ_k . Tables of ζ values are available from the literature.²⁵⁻²⁷ Introduction of the one-center approximation and the ζ_k parameter into equation (9) yields

$$\langle \psi_{a_1} | H'_y | \psi_{b_1} \rangle = -i \sum C_i^{a_1} C_j^{b_1} \zeta_k \langle \varphi_i^{a_1} | \hat{L}_k^y | \varphi_j^{b_1} \rangle \quad (10)$$

where $\varphi_i^{a_1}$ and $\varphi_j^{b_1}$ are the angular parts of the atomic orbitals which comprise the ψ_{a_1} and ψ_{b_1} molecular orbital functions (the radial parts having been incorporated into the ζ_k). The summation is over one-center terms only.

Operation of the \hat{L}_q ($q=x, y, z$) operator on an atomic orbital results in the rotation of that orbital around one of the cartesian axes. If the new orbital is denoted φ' , the integral in the right side of (10) is

$$\langle \varphi_i^{a_1} | \varphi_j^{b_1} \rangle$$

which is an overlap integral.

Tables describing the result of the \hat{L}_q ($q = x, y, \text{ and } z$) operator on s, p, d, and f orbitals are given in reference 11, p. 347 and Appendix H. These tables were used with the nitrite molecular orbitals in Table 6 to calculate the anion spin-orbit coupling integrals. The spin-orbit coupling integrals for silver may be calculated from the tables alone (ζ values from Reference 5). The results are given in Table 8.

C. TRANSITION DIPOLE MOMENTS:

Transition dipole moment integrals in Table 5 (e.g., $\langle a | \vec{r} | m \rangle$), are derived from expressions such as equation (8). In equation (8), the transition moment is

TABLE 8

$$\langle yz | z^2 \rangle = -i1581 \quad \langle xz | z^2 \rangle = 1581$$

$$\langle M^* | H' | m \rangle$$

$$= 0$$

¹Spin-orbit coupling constants are: Oxygen, $\zeta_{2p} = 152 \text{ cm}^{-1}$; Nitrogen, $\zeta_{2p} = 70 \text{ cm}^{-1}$; Silver, $\zeta_{5p} = 613 \text{ cm}^{-1}$, $\zeta_{4d} = 1826 \text{ cm}^{-1}$.

$$\hat{M} = \langle {}^1\Psi_{\text{CT}} | \Sigma e \hat{\mathbf{r}}_i | {}^1\Psi_0 \rangle. \quad (11)$$

The integral is evaluated in the following manner: First, the configuration wave functions ${}^1\Psi_{\text{CT}}$ and ${}^1\Psi_0$ are expressed as Slater determinants (Table 1). Since the $e\hat{\mathbf{r}}$ operator is a one-electron operator, the only non-zero matrix element in the expansion of equation (11) will contain the two molecular orbitals which differ between ${}^1\Psi_{\text{CT}}$ and ${}^1\Psi_0$,²³

$$\begin{aligned} \text{thus } \hat{M} = \langle {}^1\Psi_{\text{CT}} | \Sigma e \hat{\mathbf{r}}_i | {}^1\Psi_0 \rangle &= \langle \frac{1}{\sqrt{2}} (| \bar{a} \bar{m}^* \bar{m} \bar{m} | + | m (\bar{a} \bar{m} \bar{m}) |) | \Sigma e \hat{\mathbf{r}}_i | | a \bar{a} \bar{m} \bar{m} | \rangle \\ &= \frac{1}{\sqrt{2}} (\langle | \bar{a} \bar{m}^* \bar{m} \bar{m} | | \Sigma e \hat{\mathbf{r}}_i | | a \bar{a} \bar{m} \bar{m} | \rangle \\ &\quad + \langle | m^* \bar{a} \bar{m} \bar{m} | | \Sigma e \hat{\mathbf{r}}_i | | a \bar{a} \bar{m} \bar{m} | \rangle) \\ &= \frac{1}{\sqrt{2}} (\langle \bar{m}^* | e \hat{\mathbf{r}} | \bar{a} \rangle + \langle m^* | e \hat{\mathbf{r}} | a \rangle) \\ &= \sqrt{2} \langle m^* | e \hat{\mathbf{r}} | a \rangle \end{aligned}$$

as found (without the electronic charge e) in Table 5.

Second, the molecular orbitals m^* and a are expressed as linear combinations of atomic orbitals, yielding

$$\hat{M} = \sum_i \sum_j C_i^{m^*} C_j^a \langle \varphi_i^{m^*} | e \hat{\mathbf{r}} | \varphi_j^a \rangle. \quad (12)$$

The analytic forms for the resultant functions $\langle \varphi | \hat{\mathbf{r}}$, where $\hat{\mathbf{r}} = x, y$, or z and φ is a Slater-type ns , np , or nd ($n = 2$) orbital, are available from reference 11, Appendix F. The integral in equation (12) evolves into an overlap integral. In order to facilitate computation, the coordinate $\hat{\mathbf{r}}$ was always assumed to act upon the anion atomic orbital. Care was taken to preserve the sign of the overlap. The overlaps were taken from the output of a Zimol calculation. For the sake of thoroughness, all symmetry allowed anion \leftrightarrow metal transitions were calculated (Table 9).

D. MOLECULAR DIPOLE MOMENTS:

Static molecular dipole moments are needed for the calculation of expression 'e' listed in Table 5. The dipole moments were computed in the collapsed-core, point charge approximation using the output of the Zevc program:

$$D = \sum_i \vec{R}_i q_i$$

where \vec{R}_i is the coordinate of the i^{th} atomic center, and q_i is the net atomic charge of that center. The values of q_i and the resulting dipole moments for silver nitrite in Structures I and II (for the ground electronic state) are given in Table 10.

The dipole moment of the silver nitrite molecule in the excited state ($^3\Psi_{A*}$) is needed for expression 'a' of Table 5. This quantity is difficult to obtain, either experimentally or by calculation. For this reason, this dipole moment was assumed to be the same as that of the ground electronic state.

E. ENERGY DENOMINATORS:

A number of configuration energies are required for the perturbation coefficients in the expressions on Table 5. Considerable care must be taken to ensure that reasonable values be obtained for these energies.

The only whole-molecule silver nitrite calculations available are the extended Huckel programs Zipmol and Zevc. Several problems occur in these calculations: First, the program outputs refer to

TABLE 10

orbitals which are linear combinations of nitrite atom and silver atomic orbitals, while the perturbation equations have been developed for a formalism using distinct nitrite and silver orbitals. Second, they do not evaluate any exchange integrals and thus assume a degeneracy of singlet and triplet states. Thirdly, extended Huckel calculations are not noted for their accuracy in the calculation of excited state energies. Consequently, these calculations are not particularly suited to our needs.

The CNDO/S-C.I. program is not parameterized for silver, nor does it calculate exchange integrals for excitations of $n\pi^*$ type. It is, however, capable of calculating rather closely the transition energies of the nitrite ion $S_n \leftarrow S_0$ ($n \leq 3$) and $T_1 \leftarrow S_0$ transitions (Table 11).

We have chosen to remain as empirical as possible. All energies not available from experiment were judiciously interpolated from the computational data. For purposes of expediency, we have also assumed that orbital energies are approximately equal to electronic transition energies.

The term ${}^1E_{A*}$ in Table 5 may refer to the energy of the excited state produced by excitation out of any of the three highest occupied nitrite orbitals (a_1 , a_2 , or b_2). These states will be designated $\Psi_{A*}(b_1 \leftarrow a_1)$, $\Psi_{A*}(b_1 \leftarrow a_2)$, and $\Psi_{A*}(b_1 \leftarrow b_2)$, respectively. Experimental energies for the $b_1 \leftarrow a_1$, $b_1 \leftarrow a_2$, and $b_1 \leftarrow b_2$ electronic transitions were taken from reference 1 and assigned as the energies of the ${}^1E_{A*}$ -

⁴Singlet-singlet transition energies from S. J. Strickler and M. Kasha, J. Am. Chem. Soc., 85, 2899 (1963), singlet-triplet transition energy from H. J. Maria, A. Wahlborg, and S. P. McGlynn, J. Chem. Phys., 49, 4925 (1968).

$(b_1 \leftarrow a_1)$, ${}^1E_{A*}(b_1 \leftarrow a_2)$, and ${}^1E_{A*}(b_1 \leftarrow b_1)$ configurations, respectively.

Note that the nomenclature has been extended.

In a similar manner, the ${}^3E_{A*}(b_1 \leftarrow a_1)$ energy was taken from the nitrite ion $T_1 \leftarrow S_0$ transition energy maximum in water solution;²⁹ the energy of the $p \leftarrow d$ transition of Ag^+ in water³⁰ was taken for ${}^1E_{M*}(p \leftarrow d)$; and, the energy of the transition assigned as charge-transfer in $AgNO_2^B$ was taken for ${}^1E_{CT}(s, p \leftarrow a_1)$. The silver 5s and 5p orbitals are assumed to have the same energy.

The values of ${}^1E_{CT}(s, p \leftarrow a_2)$ and ${}^1E_{CT}(s, p \leftarrow b_2)$ were generated by assuming that these energies increase relative to the ${}^1E_{CT}(s, p \leftarrow a_1)$ energy by exactly the same amount as the corresponding nitrite transitions which terminate on the b_1 orbital. For example, ${}^1E_{A*}(b_1 \leftarrow a_2)$ is 2.48 eV higher than ${}^1E_{A*}(b_1 \leftarrow a_1)$. This amount is added to the energy of ${}^1E_{CT}(s, p \leftarrow a_1)$ to give the value of ${}^1E_{CT}(s, p \leftarrow a_2)$.

The value for ${}^1E_{RCT}(b_1 \leftarrow d)$ was obtained by algebraic manipulation of the other energies. ${}^1E_{A*} - {}^3E_{A*}$ intervals were all taken to be $5,000\text{ cm}^{-1}$ (the experimentally observed value for the $b_1 \leftarrow a_1$ transition). The singlet-triplet intervals for E_{CT} and E_{RCT} should be much less; however no experimental data is available. Both are assumed to be $1,000\text{ cm}^{-1}$. The resulting energies are given in Table 12.

V. RESULTS AND DISCUSSION:

The numerical evaluation of all expressions derived from Table 5 are listed on Table 13, and summarized on Table 14. The following observations can be made.

A few suspected intensity-enhancing mechanisms do not contribute to the ${}^3\Psi_{A*} \leftarrow \Psi_0$ transition intensity. The metal excited states Ψ_{M*} cannot spin-orbit couple with the anion (in relation to the above singlet-triplet transition) except via two-center spin-orbit coupling integrals, which we take to be zero. Similarly, the mechanism ${}^3\Psi_{A*} + c'''\Psi_{A*}$ is ineffective because of symmetry restrictions on c''' (which contains $\langle a | H' | a \rangle$ and $\langle a^* | H' | a^* \rangle$ integrals, but $\Gamma_{\text{spin-orbit coupling}}$ does not contain Γ_{A_1} in C_{2v}).

The largest transition moments derive from expressions containing static dipole moments. (These transition moments are designated by a # in Table 14.) The expressions involved are a) and e) in Tables 2 and 5. The energy denominators in these expressions are of opposite signs. Consequently, the transition moments derived from them tend to cancel (assuming the ground state and ${}^3\Psi_{A*}$ state dipole moments are equal). If the actual dipole moment of the ${}^3\Psi_{A*}$ state were used in the calculation, then the sum of the # transition moments would relate to the change of the dipole moment upon excitation.

The mixing of singlet charge-transfer states into ${}^3\Psi_{A*}$ accounts for the next largest set of transition dipole moments. This results both from the small energy difference between the ${}^3\Psi_{A*}$ state

designates a static dipole moment contribution.

and the $^1\psi_{CT}$ state, and the large z-polarized transition moments ($a_1 \rightarrow p_z$ and $a_1 \rightarrow s$) which are mixed in by this perturbation. It is important to note that the large spin-orbit coupling available from the silver atom is not operative here.

The smallest transition moments arise from the mixing of $^1\psi_{CT}$ states into $^3\psi_{A*}$ or ψ_0 . The low transition moments are caused both by large energy denominators and by the small transition moments mixed in by this perturbation, notwithstanding the large silver spin-orbit coupling which occurs.

In general, the results for the two structures are about the same. The $^3\psi_{A*} \leftarrow \psi_0$ transition is polarized primarily along the z axis, with an oscillator strength of $\sim 1.3 \times 10^{-6}$ and an intrinsic lifetime³¹ of 2.2×10^{-3} seconds. Weaker transitions are calculated with x and y polarizations. The singlet \rightarrow triplet transition intensity is derived primarily from $a_1 \rightarrow p_z$ and $a_1 \rightarrow s$ charge-transfer transitions.

The experimental observation of the z polarization of the singlet \rightarrow triplet absorption⁷ in $\text{AgNa}(\text{NO}_2)_2$ has been mentioned. The experimental value of the $T_1 \leftarrow S_0$ absorptive oscillator strength' of $\sim 1.6 \times 10^{-4}$ is higher than the calculated value. Also, the experimentally measured lifetime³² of 2×10^{-4} is shorter. Both of these disparities may be due to the assumption that $\mu_{A*} = \mu_0$. If $|\mu_0| = |\mu_{A*}| = 1e\text{\AA}$ (4.8 D) for the $^1B_1 \leftarrow ^1A_1$ transition, the resulting oscillator strength conferred on the $T_1 \leftarrow S_0$ transition would be 5.65×10^{-6} . Also, the wave functions employed for the nitrogen and oxygen atoms (from CNDO/s-C.I.) were not parameterized for a calculation which

included a heavy atom such as silver.

The experimental data for pure silver nitrite⁸ is not similar to that of $\text{AgNa}(\text{NO}_2)_2$.⁷ In the former, $T_1 \leftarrow S_0$ absorption occurs along all three axes with relative intensities of $x > y > z$, while in the latter the absorption is confined solely to the z axis. This is not indicated by our calculations. The quality of data is considerably higher, however, in the latter as compared to the former.

The conclusion that the singlet \rightarrow triplet transition in silver nitrite contains significant contributions from charge-transfer transitions remains. The existence of an intense transition in the spectrum of silver nitrite tentatively assigned as charge-transfer⁸ has been mentioned.

According to this model, the mechanism of $T_1 \leftarrow S_0$ intensity enhancement in silver nitrite is quite different than that which is operative in sodium nitrite. In the latter molecule, no significant possibility of spin-orbit coupling or charge-transfer with the cation exists, and the $T_1 \leftarrow S_0$ transition is not intense. ($f \sim 8 \times 10^{-4}$).⁴

VITA

Thomas Preston Carsey was born in Monterrey, Mexico, on January 24, 1946. He was graduated from Hatch Valley High School, Hatch, New Mexico, in 1963. He entered the New Mexico State University in 1963 and graduated from that Institution with a B.Sc. degree in Chemistry in 1969. He attended the graduate school of New Mexico State University from 1970 to 1971.

In September, 1972, he joined the Graduate School at the Louisiana State University. He is presently a candidate for the degree of Doctor of Philosophy.

On December 31, 1970, he married the former Susan Pamela Wier. They have two children.
